

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

DICTIONARY

OF

MECHANICAL SCIENCE,

Arts, Manufactures,

AND

MISCELLANEOUS KNOWLEDGE.

COMPRISING

THE PURE SCIENCES OF MATHEMATICS, GEOMETRY, ARITHMETIC, ALGEBRA, &c.;—THE MIXED SCIENCES OF MECHANICS, HYDROSTATICS, PNEUMATICS, OPTICS, AND ASTRONOMY;—EXPERIMENTAL PHILOSOPHY;—THE FINE ARTS;—AGRICULTURE, AND ITS IMPLEMENTS;—MANUFACTURES, AND THEIR VARIOUS PROCESSES;—COMMERCE AND DOMESTIC ECONOMY;—NATURAL HISTORY;—WITH BIOGRAPHICAL AND HISTORICAL NOTICES OF EMINENT MEN, WHO HAVE ADORNED SCIENCE BY THEIR INVENTIONS AND DISCOVERIES.

Illustrated with many Hundred Engravings.

Studies serve for delight, for ornament, and for ability: they perfect nature, and are perfected by experience. Crafty men condemn studies, simple men admire them, and wise men use them. Read not to contradict and confute, nor to believe and take for granted; nor to find talk and discourse, but to weigh and consider. Some books are to be read only in parts; others to be read, but not curiously; and some few to be read wholly, and with diligence and attention.

LORD BACON

BY ALEXANDER JAMIESON, LL.D.

VOL. II.

LONDON:

PRINTED FOR HENRY FISHER, SON, AND CO. NEWGATE-STREET.

1829.

1900, Aug - 1

8-47
49-56
22-2

L.

L, or **l**, the eleventh letter of our alphabet; a numeral denoting 50; and with a dash over it, 50,000.

LA, in Music, the syllable by which Guido denotes the last sound of each hexachord; if it begins in C, it answers to our A, if in G to E; and if in F to D.

LABDANUM, or **LADANUM**, is a resin obtained from the surface of the cystus Creticus, a shrub which grows in Syria, and the Grecian islands. It is collected while moist, by drawing over it a kind of rake, with thongs fixed to it, from which it is afterwards scraped. When it is very good, it is black, soft, and has a fragrant odour and a bitterish taste. Water dissolves about a twelfth part of it, and the matter taken up possesses gummy properties. When distilled with water, a small quantity of volatile oil arises. Alcohol may also be impregnated with the taste and odour of labdanum.

LABEL, in Navigation, a thin brass ruler used in taking altitudes. In Law, a slip of paper or parchment that holds the seal. In Pharmacy, directions for the use of medicine.

LABIAL LETTERS, those pronounced chiefly by means of the lips.

LABORATORY, in Military affairs, signifies that place where all sorts of fireworks are prepared, both for actual service and for experiments, viz. quick matches, fuzes, port-fire, grape shot, case shot, carcasses and grenades, cartridges, shells filled, and fuzes fixed, wads, &c. &c.

LABORATORY, in Chemistry, the room in which the artist keeps his utensils, and makes his experiments.

LABOURING, implies pitching or rolling heavily in a turbulent sea, an effect by which the masts and hull of the ship are greatly endangered; because, by the rolling motion, the masts strain upon their shrouds with an effort which increases as the sine of their obliquity; and the continual agitation of the vessel often loosens her joints, and makes her extremely leaky.

LABYRINTH, among the ancients, was a large intricate edifice cut into various aisles and meanders, running into each other, so as to render it difficult to get out of it. There is mention made of several of those edifices among the ancients; but the most celebrated are the Egyptian and Cretan labyrinths.

LAC is a resinous substance, the production of an hemipterous insect, which is found on three or four different kinds of trees in the East Indies. The head and trunk of the lac insect seem to form one uniform, oval, and compressed red body, about the size of a flea. The antennæ are thread-shaped, and half the length of the body. The tail is a little white point, from whence proceed two horizontal hairs as long as the body. These insects pierce the small branches of the trees on which they feed; and the juice that exudes from the wounds is formed by them into a kind of cells, or nidus for their eggs. Lac is imported into this country adhering to the branches in small transparent grains, or in semi-transparent flat cakes. Of these the first is called *stick lac*, the second *seed lac*, and the third *shell lac*. On breaking a piece of stick lac, it appears to be composed of regular honeycomb-like cells, with small red bodies lodged in them; these are the young insects, and to them the lac owes its tincture, for when freed from them its colour is very faint. Seed lac is the same substance grossly pounded, and deprived of its colouring matter, which is used by dyers and for other purposes; and shell lac is the cells liquefied, strained, and formed into thin cakes.

Lac Sulphuris, in Medicine, a sulphur, separated by acid from its alkaline solution, which renders it milder. See **SULPHUR**.

LACCIC ACID, in Chemistry, a white or yellowish production of insects, called white lac. Some of this substance, brought from Madras, was analyzed, and found to bear a considerable analogy to bees' wax. The component parts of this acid are carbon, hydrogen, and oxygen.

LACE, in Commerce, a work composed of many threads of gold, silver, or silk, interwoven one with the other, and worked upon a pillow with spindles, according to the pattern designed;

the open work being formed with pins, which are placed and displaced as the spindles are moved. For cleaning gold lace and embroidery when tarnished, alkaline liquors are not to be used, for they corrode the silk, and change or discharge its colour. Soap also alters the shade of certain colours. But spirit of wine may be used without any danger of its injuring either the colour or quality; and in many cases proves as effectual for restoring the lustre of the gold, as the corrosive detergents.

LACE Bone, a lace made of fine linen, thread, or silk, much in the same manner as that of gold and silver. The pattern of the lace is fixed upon a large round pillow, and pins being stuck into the holes or openings in the pattern, the threads are interwoven by means of a number of bobbins made of bone or ivory, each of which contains a small quantity of fine thread, in such a manner as to make the lace exactly resemble the pattern.

LACERTA, the *Lizard*, was added by Hevelius to the old constellations. *Boundaries and Contents*: north by Cepheus, west by Cygnus, south by Pegasus, and east by Andromeda. In general it lies between Cygnus and Andromeda, and contains sixteen stars, three of the fourth magnitude, the remainder being smaller.

LACHRYMATORY, in antiquity, a vessel wherein were collected the tears of a deceased person's friends, and preserved along with the ashes and urn. They were small glass or earthen bottles, chiefly in the form of phials. At the Roman funerals, the friends of the deceased, or the *præfixæ*, women hired for that purpose, used to fill them with their tears, and deposit them very carefully with the ashes, in testimony of their sorrow, imagining the manes of the deceased were thereby greatly comforted. Many specimens of them are preserved in the cabinets of the curious, particularly in the British Museum.

LACK OF RUPEES, is 100,000 rupees; which, at 2s. 6d. each, amounts to £12,500 sterling.

LACTATES, combinations of earths and alkalies, &c. with the lactic acid.

LACTATION, among medical writers, denotes the *giving suck*. The mother's breast, if possible, should be allowed the child, at least during the first month; for the child is thus peculiarly benefited by what it sucks, and the mother is preserved from more real inconveniences than the falsely delicate imagine they would suffer by compliance herewith; but if, by reason of an infirm constitution, or other causes, the mother cannot suckle her child, let dry-nursing, under the mother's eye, be pursued.—When women lose their appetite by giving suck, both the children and themselves are thereby injured: wet nurses are to be preferred, who, during the time they give the breast, have rather an increased appetite, and digest more quickly; the former are apt to waste away, and sometimes die consumptive. In short, those nurses with whom lactation may for a while agree, should wean the child as soon as their appetite lessens, their strength seems to fail, or a tendency to hysteric symptoms is manifest.

When the new-born child is to be brought up by the mother's breast, apply it thereto in ten or twelve hours after delivery; thus the milk is sooner and more easily supplied, and there is less hazard of a fever than when the child is not put to it before the milk begins to flow of itself. If the mother does not suckle her child, her breasts should be kept so warm with flannel, or with a hare-skin, that a constant perspiration may be supported; thus there rarely will arise much inconvenience from the milk. The child, notwithstanding all our care in dry nursing, sometimes pines if a breast is not allowed. In this case a wet nurse should be provided; if possible, one that has not been long delivered of a child. She should be young, of a healthy habit, and an active disposition, a mild temper, and with breasts well filled with milk. If the milk is good, it is sweetish to the taste, and totally free from saltiness; to the eye it appears thin, and of a bluish cast.

LACTIC ACID. By evaporating sour whey to one-eighth, filtering, precipitating with lime-water, and separating the lime by oxalic acid, Scheele obtained an aqueous solution of what he supposed to be a petullar acid, and called it lactic acid. Boissieu Lagrange has since examined it more narrowly, and concluded it to consist of acetic acid, muriate of potash, a small portion of iron, and animal matter.

LACTIFEROUS, an appellation given to plants abounding with a milky juice, as the sowthistle and the lily. The name of *lactiflous*, or *lactescens*, is given to all those plants which abound with a thick coloured juice, without regarding whether it is white or not. Most lactiferous plants are poisonous, except those with compound flowers, which are generally of an innocuous quality. Of the poisonous lactescent plants the most remarkable are *sium*, *agave*, *maple*, *burning thorny plant*, *castanea*, *colandria*, *spurge*, *prickly poppy*; and the plants of the natural order *conifera*, as *swallow-wort*, *apocynum*, *cynanchum*, and *cethera*. The bell-shaped flowers are partly noxious, as *cardinal flower*; partly innocent, as *campanula*. Among the lactescent plants with compound flowers, that are innocent in their quality, may be mentioned *dandelion*, *pinks*, *hyssop*, *wild lettuce*, *gum ambery*, *hawkweed*, *bastard hawkweed*, *hypochaeris*, *goat's beard*, and most species of *lettuce*; we say most species, because the prickly species of that genus are said to be of a very virulent and poisonous nature; though Mr. Lightfoot denies this, and affirms, that they are safe and gentle opiates; and that a syrup made from the leaves and stalks is much preferable to the common diacodium.

LACTOMETER, the name of an instrument used for the purpose of ascertaining the different qualities of milk, from its specific gravity compared with water, and its degree of temperature under various circumstances. It was invented by M. Denis, mathematical instrument maker, of Liverpool, but is yet in its infancy.

LACTUCA, *Lettuce*, a genus of the syngenesia polygamia aequalis class and order of plants. Natural order of compositae semiboscose. *Eleocharis* Jussieu. There are eleven species; of *L. sativa*, or common garden lettuce, there are fifteen varieties.

LACUNAR, in Architecture, an arched roof or ceiling, more especially the planking or flooring above porticos or piazzas.

LADDER, a well-known convenience; of which there are a great number. In a ship, ladders serve as stairs whereby to ascend or descend from one deck to another; and are distinguished by epithets, according to the several hatchways or other parts of a ship wherein they are situated.

Scaling LADDERS, in the Military art, are used in scaling when a place is to be taken by surprise. They are made several ways: in England, they are made of flat staves, so that they may move about their pins, and shut like a parallel ruler, for conveniently carrying them: the French make them of several pieces, so as to be joined together, and to be made of any necessary length; sometimes they are made of single ropes, knotted at proper distances, with iron hooks at each end, one to fasten them up the wall above, and the other in the ground; and sometimes they are made with two ropes, and staves between them, to keep the ropes at a proper distance, and to tread upon. When they are used in the action of scaling walls, they ought to be rather too long than too short, and to be given in charge only to the stoutest of the detachment.

Thompson's Mechanical Ladder.—This ladder is a very ingenious contrivance, invented by a gentleman of the name of Thompson, and called by him the mechanical ladder. A A in the accompanying sketch, denote parallel ropes stretched and placed for the purpose of steadily conducting a seat or carriage C, in which a man may sit, and descend from the upper to the lower points of A A; these lines may be placed either in a perpendicular or inclined position; but an inclined position, forming an angle of about twenty degrees with the perpendicular, will in general be found most eligible. The carriage C may be connected by ropes, by rings, loops, or any kind of bearing parts which will confine it to a regular ascent and descent. It is connected with the counterpoise or plane of reaction, E, by a rope passing over the pulley D. B B represents a ladder for the workmen to ascend.

The manner of working this machine is as follows: the workman ascends by B B, and places himself in the carriage C, in which his weight (by preference) forms nearly an equilibrium with the weight E; which may, for example, be imagined a basket of coals. Either by taking hold of the leading ropes, or of a rope passing downwards for that purpose, he causes the carriage to descend briskly, which at the same time brings up E. He then quits the carriage, and at that time, E (which we may suppose to have been emptied by another assistant by reversing it (or otherwise) being somewhat heavier than C, descends again, and raises C to its first situation, and by the time E is again filled, the workman is ready at the top of the ladder, where he enters the carriage, and raises a second load; and in this way the work may be continued at pleasure. It is evident that this work may be performed by two or more workmen ascending and descending in succession by means of the same ladder; or, if more convenient, by more ladders than one; and in case it should be desired to lift the body E through a greater space than is to be ascended by the workmen upon B B, the purpose may be effected by fixing D higher, and causing two carriages to descend in succession along the ropes A A, though this plan is not particularly to be recommended.

The rope D E may also be wound on a barrel, and the rope D C on another, or similar barrel, both on the same axis. The parts of the machine A A, may instead of ropes be wooden or metallic sliders.

This machinery, the inventor observes, is applicable to drawing, driving, forcing, impressing, or moving bodies of every description, and that in such applications of it, no other variations in the construction, connexion, or method of working it, will be needful, than such as any person possessing an ordinary acquaintance with mechanical operations, may execute with facility.

The vulgar objection to the plan is ascending the ladder, yet this is its chief recommendation, for it is the easiest method of raising a weight. The truth of this assertion will be ascertained from the following statement.

If it be required to raise a sack of corn, a basket of coals, or any other equal weight, to the height of forty feet, (more or less) no method can be so easy to the person who is to raise the weight, as to ascend stairs or a ladder unencumbered, and to raise the sack, &c. by his own weight. By no other exertion of his own, nor by the assistance of any mechanical powers, can he perform the same operation in the same time. It must consequently be the easiest mode of raising a weight, or it could not be done in the shortest time. If it is easier in one operation, it must be equally so in any number of operations. If it is easier for one man, it must be equally so where any number of men can be employed to work together in raising heavy weights, and where this principle can be introduced. If it is easier, it must be cheaper. The labour consists in ascending the ladder, and in this exertion the man's muscular powers are all in action at the same time; not partially used, as in most other modes of raising weights. His strength may be combined with his gravity in his descent, and if opposed by the least possible friction, he cannot work with greater advantage.

Desaguliers states the maximum of a man's power as under: One man 500 pounds, 12 feet, 1 minute. The weight raised was water in a bucket. The man, who was very powerful, ascended stairs with a weight about his own person, which, together with his own, was equal to the water, and placed himself on or in an empty bucket, which was suspended by a rope passing over a pulley, and fastened to the bucket containing the water below, and raised it in the time. The man was so exhausted, that he could not repeat the operation.

The following experiment has often been exhibited by means of the present invention. One man, 1500 pounds, 12 feet, 1 minute. And this difference arises from the man's strength being combined with his gravity, and the facilities which the two parallel ropes afford him, to gain velocity by a slight exertion of his arms to arrest his descent, and quickly to re-ascend the ladder. If a man weighs 14 stone, or 196 pounds, and ascends the ladder eight times in a minute (which almost any active man may do) it is clear that he can raise eight times his own weight, or 1568 pounds.

The steps of the ladder being one foot apart (that stride being found most agreeable to the labourers) if a man ascends as slowly as possible, that is, at the rate of one foot in each second, he will ascend five times in a minute to the height of twelve feet; and if he weighs twelve stone, or 168 pounds (the average weight of a labouring man) he will raise his weight five times, or 840 pounds in that time. He will probably consume ten seconds in ascending, and one or two seconds in descending, and raising the weight. He cannot work slower. Applying this rate of work, the result of one man's power for one hour in raising the under-mentioned articles will be—

Coal, 10 chaldrons	20 feet.
Malt, Barley, Oats, &c. 90 quarters	20 feet.
Bricks, 6000 quarters	20 feet.
Water, 3000 gallons	20 feet.

When the distance is doubled, the weight raised during the same time, will be one-half.—The following weights have already been raised—

	Men.	Fet.	Hours.	Mts.
Coal, 240 chaldrons	2	6½ to 21	17	7
Bricks, 22,000	2	40	7	30
Ditto, 6000	2	40	1	0
Ditto, 1500	2	40	0	12

There are four men employed to raise a basket of coals up the river Thames, and six on many parts of the coast. It has hitherto (in 1810) been found impossible to establish, or even try this plan on board of any sailer in the river Thames; but it has been used at Brighton, where one of Latham's ships was discharged by it, with four men short of the usual complement; and in rather less than the usual time; only four men being employed to work in the hold, they could not fill the basket faster, or the vessel would have been discharged in half the usual time. The two men who worked the machine, walked nearly half of the time for a supply, and could have raised 30 chaldrons per hour instead of 12, the quantity with which they were supplied.

This plan has for a considerable time been established at the East India Docks, where all the Indianmen are discharged by it. The first ship on board of which it was tried, was the Fort William, laden with bales of cotton, weighing about two hundred and three-quarters each. The bales were raised by two men only. The Porcher was delivered at the same time by the old plan, and contained a similar cargo; each bale was raised by six men. From the Fort William 5632 bales were delivered in 17 days; from the Porcher, 5022 in 20 days; leaving an advantage of four men, three days, and a surplus of 510 bales in favour of the Fort William. The men who raised the bales on board the Fort William stood still nearly half the time, as the weight could not pass the bales quicker through the scales. The men who raised the bales from the Porcher were fully employed, and exerted themselves to the utmost, with the hope of preventing the establishment of the new plan.

The inventor of this machine took out a patent for it; the specification of which is dated March 20, 1809. He offered the use of his invention to the City of London, without the reservation of any remuneration to himself, stipulating only that a part of the saving arising from it might be devoted to a fund for bettering the present and future condition of the men, to whose labour it was chiefly applicable; so as eventually to establish some asylum or provision for them and their families, when age or accident might have disabled them from working.

* The scale in baskets similar to those used on the river Thames.

† The bricks, two beds, or about 24 at a time.

The advantages derivable from the machine, were confirmed before Sir Charles Flower, the Lord Mayor in 1809, by the affidavits of two men who used it; by which it appeared that they had actually been able to perform with it more work than had ever been done by any four men in the same time. The inventor, in his memorial to the Lord Mayor and Court of Aldermen, observes, "that any man may work by his plan, no drilling being required; and as it is merely an improvement of the old principle, it should not be regarded as the substitution of any other power for that of man, as steam, horse-power, &c."

The foregoing statements we have extracted from a very useful work in two volumes, called "The Mechanic, or Compendium of Practical Inventions," in which a description of a great number of very useful inventions may be found.

LADEN, the state of a ship when she is charged with a weight or quantity of materials equal to her tonnage or burden. If the goods, with which she is laden, be extremely heavy, her burden is determined by the weight thereof; but if light, she carries as much as she can stow, for the purposes of navigation. As a ton measure is generally estimated at 2000 lbs in weight, a vessel of 200 tons ought accordingly to carry a weight equal to 400,000 pounds; therefore, when the matter of which the cargo is composed is specifically heavier than the water in which she floats,—or, in other words, when the cargo is so heavy that she cannot float high enough with so great a quantity of it as her hold will contain,—a diminution thereof becomes absolutely necessary.

LADY. This title is derived from two Saxon words, which words have in time been contracted into the present appellation. It properly belongs only to the daughters of earls, and all of higher rank; but custom has made it a word of complaisance for the wives of knights, and of all eminent women.

LÆTIA, a genus of plants belonging to the polyandria class, and in the natural method ranking with those of which the order is doubtful.

LAGURUS, a genus of plants belonging to the triandria class, and in the natural method ranking under the fourth order, gramina.

LAIITY, the people, as distinguished from the clergy; see **CLERGY**. The lay part of his majesty's subjects is divided into three distinct states; the civil, the military, and the maritime. See **CIVIL**, **MILITARY**, and **MARITIME**.

LAKE, a collection of waters which usually receives and discharges rivers. Of lakes, which both receive and emit rivers, we reckon three kinds, as the quantity they emit is greater, equal, or less than they receive. If it be greater, it is plain that they must be supplied by springs at the bottom; if less, the surplus of the water is probably spent in exhalation; and if it be equal, their springs just supply what is evaporated by the sun. Lakes are also divided into those of fresh water, and those of salt. Large lakes answer the most valuable purposes in the northern regions.

LALANDE, JOSEPH JEROME LE FRANCAIS, a celebrated French astronomer, was born at Bourg, in the department of L'Ain, in July, 1732. He was first intended for the bar, but his genius having been very early directed to astronomical subjects, his first intention was given up; and he followed his astronomical pursuits under the celebrated Lemonier, with the greatest success. Lalande was also an associate of the principal learned societies in Europe, and was for many years the centre of communication amongst the most celebrated of their members. After a long and useful life in the pursuit of science, he died on the fourth of April, 1807, being then in the 75th year of his age.

LAMA, the sovereign pontiff, or rather god, of the Asiatic Tartars.

LAMB, THE BARONETZ, OR TARTARIAN.—Whoever has perused the accounts of early travellers, must recollect the stories that have been copied into our ancient herbals, of Tartarian sheep growing upon stems in the earth, and thence devouring all the vegetables that came within their reach.

A tale of this kind could not fail to attract the attention of the immortal father of modern botany, who took considerable pains to investigate it, and ascertained that, in the eastern part of Chinese Tartary, there is a species of fern furnished with

thick tubers, which being surrounded on all sides with yellow wool, and thin chaffy scales, are often raised so high above the ground, that the roots beneath bear some resemblance to legs fixed in the soil.

The genus of this fern has not yet been ascertained, but it is known that the roots spread round to a considerable extent, and perhaps prevent all other plants growing near it: it is not at all surprising that the imagination of the superstitious and ignorant should transform this curious vegetable into a voracious sheep. A specimen of such botanical curiosity could not pass unnoticed by the observant but romantic Darwin; and accordingly we find him speaking of it in the following terms.

Far round the pole the flames of love inspire,
And icy bosoms feel the secret fire!
Cradled in snow, and fanned by æthereal air,
Thine, gentle *Barometes*! thy golden hair;
Rooted in earth each cloven foot descends,
And round and round her flexible neck she bends;
Crops the gray coral moss, and hoary thyme,
Og lapa with rosy tongue the melting rime,
Eyes with mute tenderness her distant dam,
Or seems to bleat, a vegetable lamb.

LAMBERT, JOHN HENRY, an eminent mathematician and astronomer, was born at Muhlhausen in Sundgau, belonging to Switzerland, Aug. 29, 1728. His parents being poor, he had great difficulties to contend with in the pursuit of his studies, which he nevertheless prosecuted with unbounded success. Most of his mathematical pieces were published in a collected form by himself, in three volumes, in which almost every branch of mathematical science has been enriched with his improvements and additions. Lambert died in 1777, in the 60th year of his age.

LAMINÆ, in Physics, are extremely thin plates, of which solid bodies are supposed to be made up. These are indeed rather ideal than real; but such a conformation is frequently supposed, for the sake of simplifying the solution in a great variety of physical problems.

LAMMAS DAY, the first of August, so called, as some will have it, because lambs grow out of season, as being too big. Others derive it from a Saxon word, signifying "loaf-mass," because on that day our forefathers made an offering of bread made with new wheat. On this day, the tenants who formerly held lands of the cathedral church in York, were bound by their tenure to bring a lamb alive into the church at high mass.

LAMP, a vessel containing oil, with a lighted wick. From experiments made in order to ascertain the expense of burning chamber oil in lamps, it appears, that a taper lamp, with eight threads of cotton in the wick, consumes in one hour $\frac{3}{4}$ oz. of spermaceti oil at 2s. 6d. per gallon; so that the expense of burning 12 hours is 4s. 57 farthings. This lamp gives as good a light as the candles of eight and ten in the pound; it seldom wants snuffing, and casts a strong and steady light. A taper, chamber, or watch lamp, with four ordinary threads of cotton in the wick, consumes 0.1664 oz. of spermaceti oil in one hour; the oil, at 2s. 6d. per gallon, makes the expense of burning 12 hours only 2s. 34 farthings. Of lamps there are many constructions; a few of the most remarkable, yet useful, are:—

Argand's Lamp. This is a very ingenious contrivance, and the greatest improvement in lamps that has yet been made. It is the invention of a citizen of Geneva; and the principle on which the superiority of the lamp depends, is the admission of a larger quantity of air to the flame than can be done in the common way. This is accomplished by making the wick of a circular form, by which means a current of air rushes through the cylinder on which it is placed with great force; and, along

with that which has access to the outside, exciting the flame to such a degree that the smoke is entirely consumed. Thus both the light and heat are prodigiously increased, at the same time that there is considerable saving in the expense of oil, the combustion being exceedingly augmented by the quantity of air admitted to the flame; and that what in common lamps is dissipated in smoke, is here converted into a brilliant flame.

This lamp is now very much in use, and is applied not only to the ordinary purposes of illumination, but also to that of a lamp furnace for chemical operations, in which it is found to exceed every other contrivance yet invented. It consists of two parts, viz. a reservoir for the oil, and the lamp itself. The reservoir is usually in the form of a vase, and has the lamp proceeding from its side. The latter consists of an upright metallic tube, about one inch and six-tenths in diameter, three inches in length, and open at both ends. Within this is another tube about an inch in diameter, and nearly of an equal length; the space betwixt the two being left clear for the passage of the air. The internal tube is closed at the bottom, and contains another similar tube about half an inch in diameter, which is soldered to the bottom of the second. It is perforated throughout, so as to admit a current of air to pass through it; and the oil is contained in the space betwixt the tube and that which surrounds it. A particular kind of cotton cloth is used for the wick, the longitudinal threads of which are much thicker than the others, and which nearly fill the space into which the oil flows; and the mechanism of the lamp is such, that the wick may be raised or depressed at pleasure. When the lamp is lighted, the flame is in the form of a hollow cylinder; and by reason of the strong influx of air through the heated metallic tube, becomes extremely bright, the smoke being entirely consumed, for the reason already mentioned. The heat and light are still farther increased, by putting over the whole a glass cylinder nearly of the size of the exterior tube. By diminishing the central aperture, the heat and light are proportionably diminished, and the lamp begins to smoke. The access of air, both to the external and internal surfaces of the flame, is indeed so very necessary, that a sensible difference is perceived when the hand is held even at the distance of an inch below the lower aperture of the cylinder; and there is also a certain length of wick at which the effect of the lamp is strongest. If the wick be very short, the flame, though white and brilliant, emits a disagreeable and pale kind of light; and if very long, the upper part becomes brown, and smoke is emitted.

The Ball Cock, or Self-regulating Lamp. The principle of this lamp is that of the ball-cock. The manner in which it operates will be immediately understood from a slight consideration of the annexed figure of it, in which the several parts are represented in the situations which they respectively assume when the reservoir is empty. Those parts only are noticed which are necessary to explain the manner in which the lamp regulates itself.

A is a valve at the bottom of the reservoir, to which is attached an upright stem G, moveable vertically through holes in the projecting pieces of metal m m. To this is attached the ball, an air-tight vessel of a globular form, and so light as to float in oil, (a piece of varnished cork might be substituted.) A bent wire, moveable about as a centre, has one of its ends soldered to the ball, and the other is in contact with the valve A. E is the burner, with its socket, wick, &c. A lid covers the chamber enclosing the ball float, and which may be removed when necessary for the purpose of cleaning the inside. While the parts of the lamp are in the situation just described, let oil be poured into the reservoir. It is manifest, that it will flow through the aperture at the bottom

into the chamber containing the hollow ball, which will in consequence float, and be caused to ascend. Hence the opposite extremity of the bent wire will descend, and the valve A will follow it by its own gravity, closing the aperture, and pre-

venting the further efflux of oil. As, however, the oil is gradually consumed in the burner, it is manifest that the ball will descend, and consequently elevate the opposite extremity of the wire, together with the valve A, thus producing a fresh efflux of oil, until the whole is consumed. This lamp moreover keeps the surface of the oil in the burner always very nearly at the same distance from the flame; it projects no shadow from itself, and may be supplied with oil while burning.

Hydro-Pneumatic Lamp. The discovery of M. Dobereiner of the remarkable action of spongy platinum upon hydrogen gas, has led to the construction of an elegant lamp for producing instantaneous light. This lamp was, we believe, first made for sale by Mr. Garden, of London; but it has since been improved for by Mr. Adie, optician, in Edinburgh.—[See PLATE, MALT-KILNS AND LAMPS.]

The form given to the lamp by Mr. Garden, is shown in the plate, fig. 3, where A B is a glass globe, sitting tightly by a ground shoulder into the neck *m n*, of another globe or vessel C D. The globe A B terminates downwards in a hollow neck, *m n o p*, in the lower end of which is placed a small cylinder of zinc *o p*, into the neck of the vessel C D is fitted a brass piece *a b c*, through which the gas contained in C D can escape at the point *c*, by turning a cock *d*. An arm *e f* slides through *k*, and carries in a brass box P a piece of spongy platinum, which can be brought nearer to *c*, or removed from it, by sliding the arm *e f* through *k*. If we now pour diluted sulphuric acid into the vessel A B by the mouth at S, it will descend through the neck *m n*, compressing the air in C D, if the cock *d* is shut. The diluted acid will now act upon the ring of platinum, *o p*, and produce hydrogen gas, which, after the common air in C D is let off, will gradually fill the vessel C D. When the gas is thus collected in the vessel C D, a stream of it may at any time be discharged through the aperture C, and thrown upon the spongy platinum P, when it will produce such an intense heat as to make the platinum red-hot, and thus afford an instantaneous light. In Mr. Garden's lamp, the ring of zinc *o p*, rests upon a piece of cork, so that when the vessel C D is filled with gas, the diluted acid does not touch the zinc, and consequently no more hydrogen gas is produced; but the moment any of the gas is let off at *c*, the pressure of the head of fluid in A B overcomes the elasticity of the remaining gas in C D, and the diluted acid is forced up to the zinc, to reproduce the wasted hydrogen. By this ingenious contrivance, the diluted acid is pressed up against the zinc when more hydrogen is wanted, and withdrawn from it when the vessel C D is full. The form given to the lamp by Mr. Adie, of Edinburgh, is shown in fig. 4, where the different parts are marked by the same letters as in fig. 3. In this construction, a cone of glass, *k*, formed on the bottom of the vessel A B, is made to hold the ring of zinc, *o p*, which remains permanently in that position.

This lamp has the advantage of greater stability, and is less liable than the other to be deranged by an accidental cause. Professor Cumming, of Cambridge, who constructed one of these lamps in December 1823, found it necessary to cover up the platinum with a test tube, or a cap, after every experiment. With platina foil $\frac{1}{4}$ of an inch in thickness, and kept in a close tube, he produced the same effect; but when the thickness of the foil was $\frac{1}{16}$ in. it was necessary to raise it previously to a red heat. These lamps, besides their extreme beauty as philosophical toys, are of great use in counting-houses, as well as in private houses, in summer.

Peck's Clock Lamp. To those who are in the habit of burning a light during the night, Peck's dial lamp may prove an acceptable companion. A B are two vessels made of tin, about $\frac{1}{4}$ inch diameter, and the same in depth, communicating at the bottom by a small tube. In A burns a floating wick; in B, a float-balanced over a cone-like rool, by a small weight hanging on a piece of fine silk; the rool should contain several grooves, and vary in diameter from $\frac{1}{4}$ to $\frac{1}{2}$ inch. The gradual

burning of the oil in A, will cause the float B to fall, thereby turning the rool, which being affixed on a wire communicating with the index through the dial, will point out the hour of the night. It is necessary to adjust the index to the true time when the lamp is lighted; and some little attention is requisite to place the dial in the proper groove on the rool, which acts as a regulator to quicken or retard the burning of the oil.—*Mech. Mag.* 1825.

The Safety Lamp, invented by Sir H. Davy, to secure miners from the destructive effects of the choke damp and the fire damp; the former consisting, for the most part, of carbonic acid gas, hovers about the lower parts of the mine, and extinguishes their lights; and the latter, which is simply hydrogen gas, occupies the superior spaces, and involves inevitable mischief, from the combustion produced by its contact with the flame of the miners' candles.

The parts of the lamp are,—A, the brass cistern, which contains the oil, pierced near the centre with a vertical narrow tube E, nearly filled with a wire which is recurved above, in the level of the burner, to trim the wick, by acting on the lower end of the wire, with the fingers: it is called the safety trimmer. B, the rim in which the wire-gauze cover is fixed, and which is fastened to the cistern by a moveable screw. C, an aperture for supplying oil, fitted with a screw or cork, and which communicates with the bottom of the cistern by a tube; and a central aperture for the wick. D, the burner, or receptacle for the wick, over which is fixed the coil of platinum wire. F, the wire gauze cylinder, which should have not less than 625 apertures to the square inch. G, the second top, $\frac{1}{2}$ of an inch above the first, surmounted by a brass or copper plate, to which the rings of suspension are fixed. I, I, I, six thick vertical wires, joining the cistern below to the top plate, and serving as protecting and strengthening pillars round the cage.

When the wire gauze safety-lamp is lighted, and introduced into an atmosphere gradually mixed with fire-damp, the first effect of the fire-damp is to increase the length and size of the flame. When the inflammable gas forms as much as 1-12th of the volume of the air, the cylinder becomes filled with a feeble blue flame, but the flame of the wick appears burning brightly within the blue flame, and the light of the wick augments till the fire-damp increases to $\frac{1}{4}$ or $\frac{1}{3}$, when it is lost in the flame of the fire-damp; which in this case fills the cylinder with a pretty strong light. As long as any explosive mixture of gas exists in contact with the lamp, so long it will give light; and when it is extinguished, which happens when the foul air constitutes as much as $\frac{1}{3}$ of the volume of the atmosphere, the air is no longer proper for respiration; for though animal life will continue where flame is extinguished, yet it is always with suffering. By fixing a coil of platinum wire above the wick, ignition will continue in the metal when the lamp is itself extinguished; and from the ignited wire the wick may be again re-kindled, on going into a less inflammable atmosphere.

Wherever workmen, however, are exposed to such highly explosive mixtures, double gauze lamps should be used; or a lamp in which the circulation of the air is diminished by a tin-plate reflector placed in the inside; or a cylinder of glass, reaching as high as the double wire, with an aperture in the inside; or slips of blue-tinted glass may be placed within the lamp; and, in this way, the quantity of fire-damp consumed, and consequently of heat produced, may be diminished to any extent. Such lamps, likewise, may be more easily cleaned than the simple wire-gauze lamps; for the smoke may be wiped off in an instant from the tin plate or glass.

If a blower or strong current of fire-damp is to be approached, double gauze lamps, or lamps in which the circulation of the air is interrupted by slips of metal or glass, should be used; or if the single lamp be employed, it should be put into a common horn or glass lantern, the door of which may be removed or open. Another improvement has recently been made, by which

its utility will be greatly increased. It consists in attaching a convex lens to the lower part of the wire gauze, which enables the miner to direct a strong light upon any particular part of the mine.

The *Rolling Lamp*,—Is easily constructed: AB we will suppose is a machine with two moveable circles, DE, FG, within it, whose common centre of motion and gravity is at K, where their axes of motion cross one another. If the lamp KC is made pretty heavy, and moveable about its axis HI, and whose centre of gravity below K is fitted within the

inner circle, the common centre of gravity of the whole machine will fall below K, and by reason of the pivots A, B, D, E, H, I, will be always at liberty to descend; hence, though the whole machine be rolled along the table, or moved in any manner, the flame will always be uppermost, and the oil cannot be spilled. The lamp may be a handsome brass or gilded ball, and the whole effect would be delightful.

The *Syphon Lamp*, an original invention, the description of which appeared some time ago in the London Mechanic's Register. A is a bottle containing oil. B a syphon, one end of which nearly touches the bottom of the bottle; and which end must be half an inch farther from the parallel line E, than the end D is from the same line. By sucking out the air at D, the oil will follow it copiously; but by drawing up the syphon (which, by a spring, introduced into the neck of the bottle, is made to remain at any height,) till the end C is only a quarter of an inch in the oil, the end D will be empty a quarter of an inch down; into which put a piece of cotton, fitting rather tightly, and after cutting it off flat, at rather more than the eighth of an inch from the tube, push down the syphon, ignite the cotton,

and this syphon lamp will give a light of a very superior clearness; which is to be attributed to the *pressing* supply of oil at the bottom of the cotton. Moreover, it is a very economical lamp. The bottle and the piece of tube, which any one can bend into a syphon, cost next to nothing; and the superior brilliancy of the flame renders it unnecessary that it should be half the usual size, and consequently a little more than half the usual quantity of oil is consumed.

LAMPÆDIAS, a term sometimes applied to denote a bearded comet.

LAMPBLACK. The finest lamp black is produced by collecting the smoke from a lamp with a long wick, which supplies more oil than can be perfectly consumed; or by suffering the flame to play against a metalline cover, which impedes the combustion, not only by conducting off part of the heat, but by obstructing the current of air. Lampblack, however, is prepared in a much cheaper way, for the demands of trade. The dregs which remain after the eliquation of pitch, or else small pieces of fir wood, are burned in furnaces of a peculiar construction, the smoke of which is made to pass through a long horizontal flue, terminating in a close-boarded chamber. The roof of this chamber is made of coarse cloth, through which the current of air escapes, while the soot remains behind.

LAMPYRIS, in Natural History, *Fire Fly*, a genus of insects of the order of coleoptera. There are nearly sixty species. The common glow worm is seen during the summer months, on dry banks about woods and pastures, exhibiting, as soon as it is dusk, vivid and phosphoric splendour in form of a round spot, of considerable size. The animal itself, which is the female insect, measures about three-quarters of an inch in length, and is of a dull earthy-brown colour on the upper parts, and beneath more or less tinged with rose-colour, with the two or three last joints on the body of a pale or whitish sulphur colour. It is from these parts that the phosphoric light proceeds. The male is smaller than the female, and is provided with wings and wing-sheaths: it is not determined whether it be luminous or not.

LANA PHILOSOPHICA, (philosophical wool,) the snowy, flakes of white oxide, which rise and float in the air from the combustion of zinc.

LANCE, a spear, or offensive weapon, borne by the ancient Cavaliers, in the form of a half pike. The lance consists of three parts; the shaft, the wings, and the dart. It is among the oldest weapons recorded in history. The invention of gunpowder has rendered this instrument of destruction less important than it was in ancient times.

LANCET, a chirurgical instrument, sharp-pointed and two-edged, chiefly used to open veins in the operation of phlebotomy, or bleeding; also for laying open abscesses, tumours, &c.

LAND, as applied to the earth generally. The constituent parts of the earth are two, the *land* and *water*. The parts of the land are continents, islands, peninsulas, isthmuses, promontories, capes, coasts, mountains, &c. This land is divided into two great continents, (besides the islands,) viz. the *eastern* and *western* continent. The eastern is subdivided into three parts, viz. Europe, on the north-west; Asia, on the north-east; and Africa (which is joined to Asia by the isthmus of Suez, 60 miles over) on the south. The western continent consists of North and South America, joined by the isthmus of Darien, 60 or 70 miles broad. A *Continent* is a large portion of land, containing several countries or kingdoms, without any entire separation of its parts by water, as Europe. An *Island* is a smaller part of land, quite surrounded by water, as Great Britain. A *Peninsula* is a tract of land every where surrounded by water, except at one narrow neck, by which it joins the neighbouring continent; as the Morea in Greece; and that neck of land which so joins it, is called an *Isthmus*: as the isthmus of Suez, which joins Africa to Asia; and the isthmus of Darien, which joins North and South America. A *Promontory* is a hill, or point of land, stretching itself into the sea, the end of which is called a *Cape*; as the Cape of Good Hope. A *Coast* or *Shore* is that part of a country which borders on the sea-side. Mountains, valleys, woods, deserts, plains, &c. need no description.

LAND Measuring.—Land is commonly measured by means of the chain and its accompaniments. The Scotch chain is 24 Scotch ells, or 74·138 English feet in length, each link being 8·89658 inches; and the English chain is 22 yards, or 66 feet in length, each link being 7·92 inches. The chain should be accompanied with

1st. Ten small iron arrows, from 12 to 20 inches in length, for sticking into the ground at the end of every chain's length; each arrow having a piece of red cloth fastened to its head, that it may be the more easily observed. 2. Three or four picket staves, from 6 to 10 feet in length, and shod with iron,

for sticking into the ground at corners, &c. to direct the sight; each staff having a red or white flag at its top, that it may be seen when placed at a distance. 3. A tape, (such as is used by artificers for measuring their work,) divided into links instead of feet, for measuring offsets, or short distances between the chain-line and the boundary of the field. 4. A cross staff, for setting off the offsets at right angles to the chain line. The cross staff may be constructed thus: Take a thick circular board of well-seasoned hard wood, about 4 inches in diameter, on which draw two straight lines cutting each other at right angles; saw these lines across about half an inch deep, and one-sixteenth of an inch wide. To this board, by means of a socket, fasten a staff shod with iron for sticking into the ground.

The dimensions of any piece of ground may be accurately ascertained by these instruments; but for greater ease and despatch, surveyors generally employ some instrument for observing angles. For that purpose, the most proper instrument is a *theodolite*, furnished with two achromatic telescopes, the different adjustments and rack-work motions, parallel plates, compass, level, &c.

The *plane table* also is often of great use in land measuring, as it affords the means of plotting on the spot, the ground as it is measured, and of detecting any errors which may be committed in the work.

Problem 1.—To measure a horizontal angle (as B A C, fig. 1.) by means of the chain.—Rule. Measure any distance, as 100 links from A to B, and there stick an arrow into the ground; measure the same distance from A to C, and there also place an arrow; then measure the distance from B to C; thus will the three sides of the isosceles triangle B A C be known; whence the angle A may be found thus:—Draw the perpendicular A x, and the point x will be in the middle of B C. Then, A B : B x :: rad : S B A x; or if B x be reduced to 1000 parts of A B, it will be = the natural sine of B A x, which being doubled, will give B A C, the angle required.

Example.—Let A B or A C be 1 chain, and B C 76·7 links, what is the angle B A C?
 $767 \div 2 = 3835 = \text{Nat. sine of } 22^\circ 33'$, which being doubled is $= 45^\circ 06' = \text{B A C}$. Answer.

Problem 2.—To measure a triangular field, (as A B C, fig. 2.) Rule. Measure the three sides with the chain; or measure the base A B and the perpendicular D C; or measure any two sides and the included angle; or measure one side, and the two adjacent angles: by adopting any of these methods, sufficient data will be obtained for constructing the figure, and ascertaining its content.

Example.—What is the area of a triangular field, the three sides of which are 806 links, 400 links, and 810 links?

Operation.

810 } 196 = 2·2968652	1·56563 = 1 2 10 18 Ans.
806 } 202 = 2·3053524	4
400 } 608 = 2·7839036	2·26252
	40
2) 2016	10·5008
1908	36
	18·0288
2) 10·3993807	
156563 = 5·1946903	

Observations. The distances are always expressed in links, and not in chains and decimals; the content therefore is found in square links; from the right of which, five figures being cut

off for decimals, the rest will be acres, and the decimal being valued, will give the roods, falls, &c.

2. The method of measuring lines with the chain is as follows:—A picket staff being stuck into the ground in the direction of the line to be measured, (if there do not appear some mark naturally in that direction,) the assistant takes the end of the chain in one hand, and the ten arrows in the other, and proceeds forward towards the staff, the master measurer, or hindmost chainman, who has the other end of the chain in his hand, standing at the beginning of the line. When the assistant has gone to the end of the chain's length, he is directed in his position by the follower waving his hand to the right or left, till the follower see him exactly in a line with the mark to be measured to; there both of them stretching the chain straight on the ground, the leader sticks an arrow into the ground at the end of it, as a mark for the follower to come up to, and advances forward another chain, being directed in his position as before; the chain being then stretched, he sticks down an arrow at the end of it, and the follower takes up his arrow. They then advance in the same manner another chain's length; and thus they proceed till all the ten arrows are in the hands of the follower, and the leader without an arrow is arrived at the end of the eleventh chain's length. The ten arrows are then conveyed to the leader, who puts down one of them at the end of his chain, and advances with the chain as before. Thus the arrows are changed from the one to the other at every ten chains length; by this means the length of the line is easily ascertained: thus, if the arrows have been twice changed, and the follower hold four arrows, and the end of the line cut off 37 links more, the whole length of the line is 2437 links.

3. The method of raising perpendiculars on the ground by means of the cross staff is as follows:—When in measuring along A B (fig. 2,) you come to about D, where you judge the perpendicular will stand, plant the cross staff there, and look through one of the slits in the direction of the chain line; then, if on looking through the other slit, it points directly to C, the place of D is right; if not, move the instrument towards B or A, till it do so; thus the point D may be accurately found.

4. The method of measuring horizontal angles by the cross staff is as follows:—Suppose the obtuse angle, B A d, (fig. 3,) were required. Plant the cross staff at A, and look through one of the slits in the direction of B, then look through the other slit, having previously sent an assistant forward a few chains with a pole to be stuck into the ground at a; measure A a, then remove the cross staff to a, placing a pole in its stead at A. Look through one of the slits to the pole at A, and then through the other slit to b, and measure a b. Then A a : a b :: Rad : T, a A b, which being added to 90° gives B A d, the angle required. Again, let the acute angle A (fig. 2,) be required. Plant the cross staff at any convenient point in A B as D, and measure A D; look through one of the slits in the direction of A, then look through the other slit, and make a pole be placed at C, where the perpendicular meets A C; measure D C. Then A D : D C :: Rad : T A, the angle required.

Problem 3.—To measure a four-sided field, (fig. 4.)—Rule. Measure the sides and a diagonal; or measure a diagonal and the two perpendiculars; or measure the sides and one of the angles; or measure the diagonals and the angle of intersection; or measure a diagonal as A C, and the angles C A B, C A D, A C B, A C D; or measure the distance of a point within the field from each of its

corners, and the angles at that point subtended by the sides of the field: any of these methods will afford sufficient data for planning the field, and determining its area.

Fig. 1.

Fig. 2.

Fig. 3.

Fig. 4.

Example.—If $AB = 598$, $BC = 439$, $CD = 657$, $DA = 320$, and $AC = 779$ links, what is the area of the field $ABCD$?

Operation 1.—To find the area of ABC .

$$\begin{array}{r} 439 \times 469 = 20711728 \\ 598 \times 310 = 24913617 \\ 779 \times 129 = 21105897 \end{array}$$

$$2) 1816$$

$$908 \dots = 29580858$$

$$2) 102312100$$

$$130498 = 51156050$$

$$\text{Area of } ABC = 130498$$

$$\text{Area of } ACD = 103532$$

$$\text{Area of } ABCD = 234030$$

2. To find the area of ACD .

$$\begin{array}{r} 779 \times 99 = 19956352 \\ 657 \times 221 = 23443023 \\ 320 \times 558 = 27466342 \end{array}$$

$$2) 1756$$

$$878 \dots = 29434945$$

$$2) 100301562$$

$$103532 = 50150781$$

$$\begin{array}{r} A. R. F. \\ 2 \quad 1 \quad 14 \text{ Ans.} \end{array}$$

Problem 4.—To measure offsets, (fig. 5).—Rule. Let A, b, c, d, e, f, B , be a boundary of a field, and AB the chain line, and

Fig. 5.

the area of the space between them required. In measuring along AB , observe when you are directly opposite to the several bends in the boundary line, as at g, h, i , &c. and measure the perpendicular offsets gb, hc, id , &c. with a tape; then calculate the area of each triangle, or trapezoid, into which the space is divided, separately, and their sum will be the whole area.

Note. When the boundary is *curvilinear*, its area may be found by the method of equidistant ordinates, as given in the next problem.

Example.—Given $Ag = 120$ links, $gb = 62$, $Ah = 220$, $hc = 40$, $Al = 280$, $id = 50$, $Ak = 364$, $ek = 38$, $Al = 478$, $lf = 82$, and $AB = 576$; what is the area of the space $AbcdefBA$?

$$\begin{array}{r} Ag \times gb = 120 \times 62 = 7440 \\ gh \times (bg + ch) = 100 \times 102 = 10200 \\ hi \times (ch + di) = 60 \times 90 = 5400 \\ ik \times (di + ek) = 84 \times 88 = 7392 \\ kl \times (ek + fl) = 114 \times 120 = 13680 \\ lB \times f = 98 \times 82 = 8036 \end{array}$$

$$2) 52148$$

$$26074 = 0 \quad 1 \quad 25.$$

Problem 5.—To find the area of any *curvilinear field*, by means of *equidistant ordinates*.—Rule. If a right line AN (fig. 6,) be

Fig. 6.

divided into any even number of equal parts, as AC, CE, EG , &c. and if from the points of division perpendicular ordinates, as AB, CD, EF , &c. be erected; also if A denote the sum of the first and last ordinates, B the sum of the even ordinates, viz. the second, fourth, sixth, &c. C , the sum of all the rest, viz. of the odd ordinates, wanting the first and last, and D the common distance of the ordinates; then will $(A + 4B + 2C) \times \frac{1}{2} D =$ the area $ABON$ nearly.

Example.—The lengths of five equidistant ordinates of an area are 10, 11, 14, 16, and the length of the whole base 20; what is the area?

Here $A = 10 + 16 = 26$, $B = 11 + 16 = 27$, $C = 14$, and $D = 6$.

Now $(A + 4B + 2C) \times \frac{1}{2} D = (26 + 108 + 28) \times \frac{1}{2} = 270$. Answer.

Note. In this example we have multiplied the sum of the ordinates by 5, and divided the product by 3, because there are in all five ordinates, and the formula compounds them into 3 terms A, B, C . Were there 20 ordinates there would be 12 terms, and we should then have $\frac{1}{2} D$ as our multiplier. In the question before us, $26 + 108 + 28 = 156$, which multiplied by 5 = 780; and this divided by 3 is 270, the answer as before.

Problem 6.—To reduce spaces consisting of several trapezoids, or triangles, to one triangle of the same area, by the parallel ruler.

—Rule. At A (fig. 7,) draw an indefinite line aAa ; lay a

Fig. 7.

parallel ruler from A to c , the 3d point, move the upper part of the ruler to b , and mark where it cuts aAa , as at 1;—from 1 lay the ruler to d , bring its lower edge down to c , and mark where it cuts aAa at 2;—from 2, lay the ruler to e , and move the upper edge to d , and mark where it cuts aAa at 3;—from 3, lay the ruler to f , and bring the lower edge down to e , and mark where it cuts aAa at 4;—from 4, lay the ruler to B , and raise the upper edge to f , and mark where it cuts aAa at 5. From 5 draw the line $5B$; then will the triangle $AB5$ be equal in area to the sum of the two triangles and four trapezoids in the given space.

Examples.—1. Reduce the space of which fig. 7 is a sketch, to a triangle of equal area, supposing the measures to be stated in the first exercise to problem 4.

2. Reduce the space of which fig. 8 is a sketch, to a triangle

Fig. 8.

of the same area, the measures being as follows: $Ag = 68$, $ib = 31$, $Ak = 118$, $kc = 15$, $Al = 146$, $ld = 40$, $Am = 181$, $me = 24$, $An = 245$, $nf = 62$, $AO = 340$, $oy = 24$, $Ap = 358$, $ph = 44$, and $AB = 418$.

Problem 6.—To measure any field.—Case 1. When the measures can be taken within the field.—Rule. Walk over the ground, and consider how it may be best laid out into triangles, trapezoids, &c. and what lines are most suitable to the purpose of accurate measurement, and will occasion least trouble in walking forward and backward. Draw an eye-sketch of the ground in your field book, measure all the necessary lines, and note them down beside the corresponding parts in the sketch; then calculate the content of each part separately in square links, and their sum reduced to acres, &c. will be the content of the field.

Case 2. When the ground is covered with wood, water, &c. so that the necessary internal lines cannot be taken.—Rule. Measure a trapezium surrounding the field, so that the lines measured may make one or more right angles with each other, and measure perpendiculars from those lines to all the angular points of the field. Thus a true plan of the field may be constructed, from which the content may be found, either by deducting the areas of the small parts without the field, from the general content of the outer trapezium, or by equalizing the sides of the figure, by the parallel ruler, by problem 5.

Fig. 9.

Thus a true plan of the field may be constructed, from which the content may be found, either by deducting the areas of the small parts without the field, from the general content of the outer trapezium, or by equalizing the sides of the figure, by the parallel ruler, by problem 5.

Example.—Find the content of the field, of which fig. 9 is a sketch, from the measures marked on the sketch.

1112 } 339 = 2-5301997	1112 } 355 = 2-5502284
900 } 551 = 2-7411516	944 } 523 = 2-7185'17
890 } 561 = 2-7489629	878 } 589 = 2-7701153
2) 2902	2) 2934
1541 = 3-1616674	1467 = 3-1664301
2) 11-1819816	2) 11-2052755
389933 = 5-5609908	400532 = 5-6026377
878 × 123 = 107964	Area of 1st triangle = 389933
200 × 132 = 26400	Area of 2d triangle = 400532
400 × 222 = 88800	Area of offsets = 125097
300 × 90 = 27000	Area of the field = 9-15562
2) 250194	
Offsets = 125997	
9-15562 acres = 9 acres 24 falls. Ans.	

Remark. Land measurers, for the sake of expedition, often measure in the field such lines only as will enable them to draw a geometrical plot of it; and having plotted it, they divide the plot into triangles, &c. the bases and perpendiculars of which they determine by the scale, and thence compute the content.

Problem 7.—To measure several fields lying contiguously to one another.—Rule. When only a few fields are to be measured, the lines may be taken in each field as directed in problem 6; but when many contiguous fields are to be measured and planned, it will be more accurate and expeditious to proceed as follows:

Select two convenient stations, as far distant from each other as may be, and from which as much as possible of the ground

Fig. 10.

to be measured may be seen;—measure with great care the distance between these stations as the principal base, noting
67.

every hedge or other remarkable object as you pass it, and measuring short perpendicular lines to the bends of such hedges, &c. as are near at hand. From the ends of this base, or from any convenient points in it, measure other lines to some remarkable object situate towards the sides of the ground, noting as before every object as you pass it. These lines, when laid down by intersections, will form one or more large triangles on the ground, on the sides of which other smaller triangles and trapezoids may be formed, till you have sufficient data for plotting and ascertaining the area of the several fields of which the ground consists.

Remark. When a field book is used, it may be divided into three columns. In the middle column may be set down the angular observations, and the distances on the chain line at which any offset or remark is made, and also the whole distance from station to station; in the side columns may be entered the offsets and remarks made on the right and left hand respectively, and sketches made of boundaries, &c.; and it will be best to begin at the bottom of the page, and write upwards.

Example.—Let the farm, of which fig. 10 is a sketch, be planned, and the content of each field found from the measures stated in the field book in the next page.

Problem 8.—To measure and plot hilly ground.—Rule. In order to ascertain the true content of a piece of hilly ground, the whole surface must be measured, as in the case of level ground; but in plotting hilly ground, the area of the base only must be taken. The length of the base line of a hill is found thus:—As radius is to cosine of the angle of acclivity or declivity, so is the surface line ascending or descending the hill to the base or plotting line.

Example.—The surface line measured up a hill is 500 links, and the angle of acclivity $15^{\circ} 10'$; what is the base or plotting line?—Answer. Rad : Cos. $15^{\circ} 10'$:: 500 : 482-58 links.

Remark. It is a very common practice among land measurers to give for the true content of hilly ground the area of the horizontal plane, instead of the real area of the surface. In defence of which practice it is usually alleged, that “since plants shoot up vertically, the vegetable produce of a swelling eminence can never exceed what would have grown from its levelled base.” But whether this be true to the extent here asserted or not, is a point for the land valuator to determine. It belongs not to the province of the land measurer; his duty obviously is, to ascertain the true area of the surface, and to leave the consideration of the value of the ground, and of its capacity for producing, to those whom it may concern.

Remarks on the Field Book.—1. The farm, of which the following is a field book, was measured as follows:—The survey was begun at A, poles being placed, in a straight line, at A, B, C, D; the distances between these points were measured; then pits being dug with a spade in the places where the poles at A and B were fixed, (which should always be done at every point where a pole is placed,) these poles were removed from A and B, and placed at E and F, in a straight line with the poles at C and D, and the measurement continued to F. The poles were then removed from C and D, and placed at G and H, in a straight line with the poles at E and F, and the measurement continued to H. Then the poles at E and F were placed at I and K, and the measurement continued to K, the end of the line. Poles were then placed at L and M, and the distance KM measured. In like manner, poles being placed at M, N, O, P, &c. in a straight line, the distance MA was measured. Poles were then placed at A, T, U, V, and the line AV measured. Poles were then placed at W, X, Y, &c. and the line VF measured. In like manner were the other lines marked in the sketch measured.

2. In planning this survey, the learner should first lay down by the scale and compasses, the large triangle A K M, and then the triangle A F V, drawing the lines with a sharp-pointed black lead pencil;—he should next mark off the several distances AB, AC, AD, &c. writing the mark O where each pole was placed;—he should next measure the offsets to the angles, &c. and where the hedges were crossed;—he should then draw the fences, house, planting, &c.; and when the whole is laid down, it should be carefully inked in, and the black lead lines rubbed out with Indian rubber,

Continued.

OF THE DIVIDING OF LAND.—Land measurers are frequently employed to divide a piece of land among sundry tenants or proprietors, in proportion to their respective claims. In order to effect which, the content of the whole must first be accurately ascertained, and then the division may be made as directed in the following problems.

Problem 9.—To cut off a certain portion from a parallelogram by a line parallel to one side.—Rule. Divide the square links in the quantity required to be cut off by the links in the given side, and the quotient will shew the height on the other sides where the line of division should be drawn.

Example.—What length of a rectangular field, whose breadth is 750 links, will make 2 acres 3 roods 25 falls?

Here, $290625 \div 750 = 387\frac{1}{2}$ links. Answer.

Problem 10.—To cut off a certain portion from a triangular field.—Rule 1. When the portion is to be cut off by a line drawn from the vertex to the base:—Divide the base in the required proportion, and draw a line from the vertex to the point so found, and it will divide the field as required. For the two triangles thus formed being of the same altitude, are to one another as their bases, which are in the required proportion.—2. When the portion is to be cut off by a line parallel to one

of the sides, as AB , fig. 11. From the content of the whole triangle CAB subtract the quantity to be cut off, viz. $aABb$, and the remainder will be the triangle Cab . Then, because the triangles CAB , Cab are similar, and similar triangles are to one another as the squares of their like sides, as the whole content CAB is to the remainder Cab , so is the square of the side CA to the square of the side Ca ; the square root of which will be the distance from C to a .

Example.—The triangle ABC contains 4 acres, and the length of AC is 895 links; at what distance from C must the line of division ab be drawn, in order to cut off $1\frac{1}{2}$ acre parallel to AB ?

$4 : 2\frac{1}{2} :: 895^2 : 500640.625$ and $\sqrt{500640.625} = 707.55$ links. Answer.

Problem 11.—To cut off any quantity from a field, by a line drawn from an assigned point in the side of it.—Rule. Set off from the given point the quantity proposed, as nearly as you can guess, and measure the ground thus set off. Then divide the difference in square links between the quantity proposed and the quantity set off, by half the length of the guess line, and the quotient will be a perpendicular, to be set off either on one side or the other of the guess line, according as the quantity set off is more or less than the quantity proposed; to which perpendicular draw a new line from the point assigned, and it will cut off the quantity required.

Examples.—1. From the point a in the field $ABCD$, fig. 12, it is required to set off 1 acre 3 roods towards the side BC .

Draw ab by guess, and measure the trapezium $abBC$; suppose you find it to be = 131,400 square links, or too little by 40600 square links, and ab to be = 566 links. Then $40600 \div 283 = 143\frac{1}{2}$ links = ex the perpendicular. Thus ax is the line of division.

2. The field $ABCDE$, fig. 13, which contains 5 acres 3 roods 18 fells, is required to be equally divided among three claimants, so that each may enjoy the benefit of the pool of water at O ?

$5a. 3r. 18f. = 586250$ square links, and $586250 \div 3 = 195416$ square links = each share. Draw EO , and set off the guess line Ox ; measure the trapezium $AEOx$; suppose you find its area to be = 200216 square links, or too much by 4800, and the length of Ox to be = 500 links. Then $4800 \div 200 = 24$ links the perpendicular from Ox to y . Thus the trapezium $OEAy$ is the first share.

From O set off a guess line to u ; measure the trapezium $OEDu$; suppose you find its area to be = 190916, or too little by 4500, and the length of Ou to be = 450 links. Then $4500 \div 225 = 20$ links, the perpendicular from u to Oz . Thus the trapezium $OEDz$ will be the second share.

The figure $OyBCz$ is the third share.

The methods of using the Plane Table and Theodolite, of Plotting, of Copying, Reducing and Enlarging Plans.—1. Before we proceed to exemplify the method of using the plane table, it may be proper to inform the learner, that the paper should be wetted with a sponge before it is laid on the table, that it may lie the more smoothly; that at every station the table should be placed as nearly horizontal as possible, by moving the legs out or in to the height wanted, and then turned round by the

socket till the north end of the needle points over the *fleur de lis* in the compass box, making the longer side of the table point N and S , and the shorter E and W ; and that before an observation is made, the instrument should be made fast, by turning the screw in the socket. This being premised in order to exemplify the use of the plane table, suppose the area and plan of the field, of which fig. 76. is a sketch, were required.

Poles being placed at the angle of the field, plant the table at A , observe that it is level, and that the needle settles over the *fleur de lis*, then screw it fast; assume a convenient part of the paper to represent A , lay the thin end of the index on the point A , look through the sight, and make the pole placed at E and the hair in the sight to coincide, draw the line AE with a black lead pencil, or the point of the compasses, and lay off the measured distance AE from a scale of equal parts; then lift the index, lay its thin edge upon the point A , and take the bearing of B , draw AB , and lay off the measured distance AB , from the same scale as before. Remove the table to B , placing its centre immediately above the hole where the pole stood, slacken the screw a little, lay the thin edge of the index on BA , and take a back sight to A , hold the index fast, and move the table round, till you see the hair in the sight and the pole at A to coincide, then screw it fast, turn the index, and lay its thin edge over the point B , and when you see the hair in the sight and the point at C to coincide, draw BC , and lay off the measured distance BC as before. At every station at which a bearing is taken, before drawing the line, observe that the index has not moved from the line on which it was laid, and draw the lines as long as possible, for the index can be laid more exactly on a long line than on a short one. Remove the table to C , and having taken as before a back sight to B , lay the thin edge of the index on C , and move the index till you see the cross hair and the pole at D to coincide, then draw the line, and lay off as before the measured distance CD . Remove the table to D , and having taken as before a back sight to C , take the bearing of DE ; if it answer, and the line DE to the measured distance DE , it proves that you have committed no error either in observing the angles or in measuring the distances, for if an error has been committed, the work will not meet. Errors may also be detected thus: leave a pole at any former station; apply the thin edge of the index to that pole and your present station, and look through the sight to the pole; then if no error has been committed, the needle will settle over the *fleur de lis* in the compass box; if it rest in any other direction, an error has been committed, which should be corrected before you proceed farther.

It may be observed, that the same field might also have been measured by either of the following methods.

The instrument might have been planted at any of the angles whence the other angles may be seen, as at A , and the bearings of B, C, D , and E from A observed, and also the distances AB, AC, AD , and AE , measured. Or the instrument might have been placed at any point within the field whence all the angles may be seen, as at O , and the bearings of A, B, C, D , and E from O observed, and also the distances OA, OB, OC, OD , and OE measured. By either of which methods it is plain the field may be plotted, and its area ascertained.*

2. When a survey is to be made with a *theodolite*, before you begin, see that the instrument be properly adjusted, the cross hairs in the telescope exactly in the centre of the table, and the level right. Then, having placed poles at the angles, &c. and brought the instrument to the place where you intend to begin, plant it there as firmly as you can, and also as level as possible, by moving the legs out and in, till within the limits of the level screws; then having levelled it exactly by means of the four screws between the brass plates fixed to the head of the legs, slacken a little the screw which holds the theodolite fast to the brass plates, and with both hands turn the instrument round on its axis, till the N end of the needle settles over the *fleur de lis* in the compass box, and set the index to 180° or 360° on the limb, according as it is divided into twice 180° or into 360° ; in the latter case the different ends of the needle will alternately agree

* A plane table, with index and sights, ball and socket, and three-legged stand, may be purchased from any mathematical instrument-maker, for from four and a half, to five and a half guineas.

with the limb, when the observations are accurate; when the theodolite is placed so that the needle and limb may correspond, the screw that holds the instrument fast to the brass plates must be made tight; and before an observation is made, the screw which holds the telescope and quadrant fast to the limb must be so slackened, that the pinion may turn the telescope easily round with the thumb and finger, till the pole placed at the second station is seen to coincide with the cross hairs in the telescope; then the screw is tightened, the bearing of the pole at the second station marked on an eye-sketch, and the distance measured. The instrument is then to be planted at the second station, its centre being placed exactly over the hole where the pole stood. Then slacken a little the screw that holds the instrument fast to the legs, and turn the theodolite till you see through the telescope the pole left at the first station; here screw it fast again, and slacken the other screw which holds the telescope and quadrant fast, to the limb; turn the pinion round to the 3d station, and mark its bearing, and so on. The magnetic needle is used as a test of the accuracy of the observations; for when no error has been committed, the degrees pointed out by the needle will correspond with those on the limb.*

3. Of the principal method of *plotting*, or making a plan of an estate, the following brief directions will give the learner some idea:—Suppose the estate measured, by taking a circuit round it with the theodolite, and filling up the interior with the chain. Lay the paper on which the plan is to be drawn very smoothly on a *drawing board*; draw a pencil line from the top to the bottom, to represent the *magnetic meridian*; about the middle of that line make a point, on which lay the centre of the circular *protractor*, so that the straight edge may coincide with the meridian line; place a weight above it, to keep it steady in that position, and draw a pencil line round the edge of it. Prick off the angles at the several stations with a *plotting pin*, marking them 1, 2, 3, &c. and remove the protractor.—Consider where the beginning of the work should be placed, so that the whole may come within the compass of the paper, and there make a mark. Lay the fore edge of the parallel ruler from the central point where the protractor lay, to the mark 1 on the pencilled circle. Move the fore edge of the ruler until it touches the point fixed on for the beginning of the plot; from which draw a pencil line in the proper direction; apply a feather-edged scale to this pencil line, so that the division 0 may be at the beginning of it, and prick off every progressive number where any offsets have been made; then turn the scale across the line, and prick off the offsets on each side of the station line; draw the boundary lines through the offset points, and the first station will be completed. Proceed thus with each of the other stations in their order, till the work comes to a close at station first. After the principal lines are laid down, proceed to the smaller objects, till you have entered every thing that ought to appear in the plan, as houses, brooks, trees, hills, gates, roads, mills, bridges, &c. When the whole is plotted, draw a line for the *true meridian*, with a *fleur de lis* pointing north in a vacant place, lay down a *scale* of the proportion you have plotted by, *title* the map in conspicuous characters, and give it a *border*.

4. A plan may be copied in various ways. One method is by means of a *copying glass*, being a large square of fine glass set in a frame which can be raised up to any angle, when the lower side of it rests on a table. The paper on which the plan is to be copied, being fixed to the plan by pins at the corners, the plan is then to be laid on the glass; and by means of a strong light placed behind the frame, every line of the plan being distinctly seen through the clean paper, may be accurately traced upon it with a black lead pencil, and afterwards inked in.

Another method is as follows: Rub some sheets of *cambric* paper over with *nut-oil*, and place the oiled paper for a few days between sheets of blotting paper. When it is thoroughly dry, lay it upon the plan, with a weight above it, and with a black lead pencil go over all the lines, till you have copied the whole upon the oiled paper. Then, having rubbed one side of a sheet of thin paper uniformly over with *lead-dust*, lay the rubbed side upon the drawing paper, and the oiled plan above

it, and trace the lines of the plan, pressing the tracer so as that the black lead under the lines may be transferred to the clean paper. Thus an accurate outline of the plan may be obtained, which may afterwards be inked in.

Another method is by the instrument called a *Pantograph*, by means of which a plan may be copied, reduced, or enlarged, very expeditiously, and with the greatest accuracy. This instrument is not only useful in reducing plans, but it may be employed with equal facility in copying, reducing, or enlarging *charts, maps, profiles, landscapes, &c.*

Another method is by dividing the plan into small squares, by means of equidistant parallel lines, intersecting one another, and then dividing the paper on which the plan is to be copied into the same number of squares, either less or greater than those on the plan, or equal to them, according as you wish the copy to be less, or greater than, or equal to, the original. Then observe in what squares the several parts of the plan are, and draw with a pencil similar parts in the corresponding squares of the copy; when the outline is thus obtained, it may be inked in.—*Davidson's Practical Mathematics.*

LAND, in the sea language, makes part of several compound terms; thus *Land-laid*, or to lay the land, is just to lose sight of it. *Land-locked*, is when land lies all round the ship, so that no point of the compass is open to the sea: *Land-mark*, any mountain, rock, &c. that serves to make the land known at sea. *Land is shut in*, signifies that another part of land hinders the sight of that the ship came from. *Land to*, or so far from shore that it can only be just discerned. *Land-ward*, a wind that in almost all hot countries blows at certain times from the shore in the night. *To set the land*, that is, to see by the compass how it bears.

LAND Breeze, a current of air, which, in many parts within the tropics, particularly in the West Indies, regularly sets from the land towards the sea during the night, and this even on opposite points of the coast.

LAND Fall, the first land discovered after a sea voyage; hence, a good land-fall implies a discovery of the land at or near the place to which the course was directed; and a bad land fall implies the contrary.

LAND Locked, is said of a harbour which is environed by land on all sides, so as to exclude the prospect of the sea, unless over some intervening land.—*To Make the Land*, is to discover it after having been out of sight of it for some time.

LAND Mark, any mountain, rock, steeple, or the like, near the sea-side, which serves to direct ships passing by, how to steer, so as to avoid certain dangers, rocks, shoals, whirlpools, &c.

LAND Waiter, an officer of the custom-house, whose duty is, upon landing any merchandise, to examine, taste, weigh, measure them, &c. and to take an account thereof. In some ports they also execute the office of a coast-waiter. They are likewise occasionally styled searchers, and are to attend and join with the patent searcher in the execution of all cockets for the shipping of goods to be exported to foreign parts; and in cases where drawbacks on bounties are to be paid to the merchant on the exportation of any goods, they, as well as the patent searchers, are to certify the shipping thereof on the debentures.

LAND Tax, one of the annual taxes raised upon the subject. See TAX. The land tax, in its modern shape, has superseded all the former methods of rating either property, or persons in respect of their property, whether by tenths or fifteenths, subsidies on land, hydages, scutages, or talliages; a short explanation of which will, however, greatly assist us in understanding our ancient laws and history. An act passes annually for the raising in general, £2,037,627. 9s. 10½d. by the above-said tax, at 4s. in the pound; whereof there shall be raised in the several counties in England, according to the proportions expressed in the act, £1,989,673. 7s. 10½d.; and in Scotland, £47,954. 1s. 2d. by an eight months' cess of £5994. 5s. 1½d. per measure, to be raised out of the land rent, and to be paid at four terms, as specified in the act, by two months' amount each time.

LANDEN, JOHN, an eminent English mathematician, was born at Peakirk, near Peterborough, in January, 1719. He became an early proficient in the mathematical sciences, and was a contributor to the *Ladies' Diary* in 1744, and continued

* Theodolites sell from five guineas to thirty pounds, and upwards, according to their construction.

his labours in that useful little performance nearly till his death, in January, 1790.

LANDSCAPE. See PAINTING.

LANDSMEN, the distinctive appellation of those on board a ship who have never before been at sea.

LANGREL, or **LANGRAGE**, a particular kind of shot, formed of bolts, nails, and other pieces of iron tied together, and forming a sort of cylinder, which corresponds with the bore of the cannon from which it is discharged, in order to wound or carry away the masts, or tear the sails and rigging of the adversary. It is seldom used but by privateers or merchantmen.

LANGUAGE. Man, of all animals, only is possessed of speech. Merely sound is, indeed, the sign of what is pleasurable or painful, and it is, for that reason, common to most other animals; for in this manner do they signify their feelings to each other. But speech indicates what is expedient or hurtful, and, a natural consequence, of what is just or unjust, it is therefore given to man, by that great Being who endowed him with consciousness; for a sense of good and evil is peculiar to man alone.

1. The most intelligent of the brute creation frequently astonish us by actions, which can proceed only from powers of intellect similar to our own; the capacity of speech, then, is the criterion of distinction between man and the brute creation. Reason, the capital faculty and characteristic of man, would, without this extensive power of communication, have remained in inactivity, its energies unexcited, and its faculties torpid.

When the influence of language upon intellect is fully and maturely considered, it will be found that the most brilliant discoveries in philosophy and science are derived from this source. If those, whose genius has dazzled the world with its splendour, had been deprived of the observations and the researches of others, they would not have risen above the level of the least cultivated, and most uninformed. Take from man the use of speech, and of visible signs, his intellectual faculties would indeed be circumscribed within very narrow limits.

2. The human voice is air sent out from the lungs, and so agitated and modified in its passage through the wind-pipe and larynx, as to be distinctly audible. The windpipe is that tube which, on touching the forepart of our throat externally, we feel hard and uneven; it conveys air into the lungs for the purpose of respiration and speech. It consists of cartilages, circular before, that they may resist external injury; but flattish on the opposite side, that they may not hurt the œsophagus, or gullet, which lies close behind, and is the tube which conveys food into the stomach. These cartilages are separated by fleshy membranes; by means of which the windpipe may be shortened or lengthened, and when necessary, incurvated without inconvenience. The upper part of windpipe is called the larynx; it consists of four or five cartilages, that may be expanded or brought together by the agency of the muscles, which operate all at the same time.

3. In the middle of the larynx there is a small aperture called the glottis, through which the breath and voice are conveyed, but which when we swallow, is covered by a lid, called the epiglottis; for if any part of our food get into the windpipe by this passage, it occasions coughing, till it is thrown out again. The best authors have determined, that the human voice is produced by two semicircular membranes in the middle of the larynx, which form by their separation the aperture termed the glottis. The space between them is not more than the tenth part of an inch in width, through which the breath transmitted from the lungs passes with considerable velocity. It gives, in its passage, a brisk vibratory motion to the membranous lips of the glottis, and thus forms the sound called voice; this is strengthened and mellowed by reverberation from the palate and other cavities in the mouth and nostrils; and as these are better or worse adapted for reverberation, the voice is more or less harmonious.

4. The origin of language is involved in much obscurity. We are informed by the sacred historian, that the rudiments of language were given to man by his Maker; for Adam named all creatures: we must not, however, imagine that this was a perfect system,—it was but the first step. It is natural to suppose, that God taught our first parents only such language as

sulted their present occasions, leaving them to enlarge and improve it as their necessities required. Supposing a period to exist, when words were uninvented or unknown, men would have had no other method of communicating their feelings to others than by the cries of passion, accompanied by such gestures, as were expressive of emotion. These are the only signs which nature teaches, and they are intelligible to all. Were two men, ignorant of each other's language, to meet together, each would endeavour to express himself by gesticulation, by signs, or by short and sudden exclamations; which would be uttered in a strong and passionate manner. These, grammarians have denominated *interjections*, and they were undoubtedly the first elements of speech.

5. When more enlarged communication became requisite, and names began to be applied to objects, the nature of the object was assimilated as much as possible to the sound of the name. To describe any thing harsh or boisterous, a harsh or boisterous sound was employed; names were never given in a manner purely arbitrary. In the *Hebrew*, the names of animals given by Adam, bear a striking analogy to the individuals they represent. In the infancy of language, nothing was more natural than to imitate, by the sound of voice, the noise produced by external objects: a number of words may be discovered, constructed upon this principle. When one sort of wind is said to *whistle*, and another to *roar*; when a serpent is said to *hiss*; a fly to *buzz*, and falling timber to *crash*; a stream to *flow*, and hail to *rattle*; the resemblance of the word to the thing signified, is plainly discernible. The native of Tahiti, (usually but improperly written Otaheite,) gives to the gun the appellation of *tick-tick-boo*, evidently imitating the cocking and report of a firelock. The *cuckoo* also derives its name from its note. These, and a host of instances in other languages, prove that words were, originally, imitative. As the multitude of terms, however, increased, and the vast field of learning was filled up, words, by a thousand fanciful and irregular methods of derivation and composition, deviated widely from the primitive character of their roots, and lost all resemblance to the objects which they were intended to represent. Words may be considered as symbols, not as imitations; as arbitrary or instituted, not natural, signs of ideas.

6. In the early ages of the world, there is every reason to suppose that the difference of the language in Europe, Asia, and Africa, was no more than a difference of dialects; and that the people of Greece, of Phenicia, and of Egypt, mutually understood each other. The oriental origin of the Latin and Greek is now generally acknowledged; and to these, the Teutonic dialects have an affinity; the Arabic, the Chaldee, the Syriac, and the Ethiopic, still bear the most striking resemblance to the *Hebrew*; in the Welsh, are many words analogous to it: the Celtic, also, has derived much from this and other eastern languages. The *Hebrew*, then, if we judge from these remarkable facts,—from the mode of its derivation, from its radicals, or from the simplicity of its structure,—must undoubtedly be considered as the primitive or parent language.

7. An eminent linguist of the present day, thinks it very likely that the original language was composed of monosyllables, that each had a distinct ideal meaning, and only one meaning; as different acceptations of the word would undoubtedly arise, either from compounding terms, or when there were but few words in the language, using them by a different mode of pronunciation, to express a variety of things. Where this simple, monosyllabic language prevailed, (and it must have prevailed in the first ages of the world,) men would necessarily have *simple ideas*, and a corresponding *simplicity of manners*. The Chinese language is exactly such as this; and the *Hebrew*, if stripped of its vowel points; and its prefixes, suffixes, and postfixes, separated from their combinations, so that they might stand by themselves, would nearly answer to this character, even in its present state. The same author, speaking of the confusion of tongues, thinks, that God caused the workmen employed in building the Tower of Babel, to articulate the same word differently,—to affix different ideas to the same term,—and perhaps, by transposing syllables, and interchanging letters, to form new terms and compounds, so that the mind of the speaker was apprehended by the hearer in a contrary sense to what was intended.

LANGUOR, among Physicians, signifies great weakness and loss of strength, attended with a dejection of mind; so that the patients can scarce walk or even stand upright, but are apt to faint away.

LANIARD, or **LANNIERS**, a short piece of rope or line, fastened to several machines in a ship, and serving to secure them in a particular place, or to manage them more conveniently: such are the laniards of the gun ports, the laniards of the buoy, the laniard of the cat-hook, &c. The principal laniards used in a ship are those employed to extend the shrouds and stays of the mast by their communication with the dead-eyes and hearts, so as to form a sort of mechanical power resembling that of a tackle. The following is the manner in which those laniards are fixed in the dead-eyes; one end of the laniard is thrust through one of the holes in the upper dead-eye, and then knotted to prevent it from drawing out; the other end is then passed through one of the holes in the lower dead-eye, whence returning upward, it is inserted through the second hole in the upper dead-eye, and next through the second in the lower dead-eye, and finally through the third holes in both dead-eyes. The end of the laniard being then directed upwards from the lowest dead-eye, is stretched as stiff as possible by the application of tackles, and that the several parts of it may slide with more facility through the holes in the dead-eyes, it is well smeared with hog's lard or tallow, so that the strain is immediately communicated to all the turns at once.

LANISTER, in Antiquity, is sometimes used to signify an executioner, but more frequently for a master gladiator, who taught the use of arms, and had always people under him ready to exhibit shows of that kind. For this purpose, they either purchased gladiators, or educated children in that art, that had been exposed.

LANIUS, the *Shrike*, in Natural History, a genus of birds of the order *picæ*. There are fifty-six species. The great shrike is about the length of ten inches, and found in France in great numbers, but rare in England. It subsists on insects and small birds, seizing the last by the throat and strangling them, and then fixing them on a thorn, from which it tears them piecemeal and devours them. To decoy them within its reach, it imitates the song of many birds, which approach, delighted by the sounds, and unsuspecting of the danger. It is a favourite bird with husbandmen, as it is considered by them a mortal enemy to rats, mice, and other species of vermin. It, however, prefers mountainous and secluded situations to the neighbourhood of mankind.

The red-backed shrike is much more frequently to be met with in this country than the last species. It is particularly fond of grasshoppers and beetles, which, as indeed various other articles of its food, it will stick upon a thorn.

LANTERN, a well known machine, of which there are many used in a ship, such as poop-lanterns, top-lanterns, signal-lanterns, store-room lanterns, powder-room lanterns, &c.

LANTERN, in Architecture, a little dome raised over the roof of a building, to give light, and serve as a crowning to the fabric.—The term lantern is also used for a square cage of carpentry, placed over the ridge of a corridor gallery, between two rows of shops, to illumine them, like that of the Royal Exchange, London.

Dark LANTERN, one with one opening, which may also be closed up when the light is to be entirely hid, or open when there is occasion for the assistance of the light to discover some object.

Magic LANTERN, an optical machine, whereby little painted images are represented so much magnified, as to be accounted

the effect of magic by the ignorant. The contrivance is briefly

this: **ABCD** is intended to represent a tin lantern, from whose side there proceeds a square tube *bnklmc*, consisting of two parts; the outermost of which, *nklm*, slides over the other, so as that the whole tube may be lengthened or shortened by that means. In the end of the arm *nklm*, is fixed a convex glass, *kl*; about *de* there is a contrivance for admitting and placing an object, *de*, painted in dilute and transparent colours, on a plane thin glass; which object is there to be placed inverted. This is usually some ludicrous or frightful representation, the more to divert the spectators.

LAPIDARY. The cutting and polishing of gems is the work of the lapidary, and is in general thus performed: The form most proper to be given to any particular gem being determined on, it is cemented to the end of a stick, and the different facets are formed by a mill contrived for the purpose. This mill is a plate of copper, or an alloy of lead and tin, to which an horizontal motion is given by very simple machinery, and the surface of which is charged either with diamond powder and oil, or with fine emery and water. A thick peg of wood, called a gange, pierced with small holes in all directions, is set upright on the lapidary's bench, close to the mill, and the process of forming the facets thus takes place. The stone is placed on the surface of the mill, the opposite end of the stick to which it is cemented being inserted in one of the holes of the gauge. In this position it is kept steady by the workman with the right hand, whilst with the other he puts the mill in motion. The skill of the lapidary depends on regulating the velocity of the mill, and pressing with more or less force on the stick, with an almost imperceptible tendency to one or other direction in different stages of the work, examining each facet at very short intervals, in order to give as great precision as possible to its size and form. This part of the business being completed, the cutting mill is taken out, and replaced by one of brass, on which the polishing is performed by means of fine emery, tripoli, and rotten-stone, exactly in the same manner as is practised in the first stage of the process for setting the facets.

LAPIDESCENT, any thing which has the faculty of petrifying, or turning bodies to a stony nature. The older naturalists speak of lapidescent juices.

LAPIS, in general, is used to denote a stone of any kind.

LAPLYSIA, or **SEA-HARE**, a genus of marine animals belonging to the class of vermes.

LAPSANA, *Nippelwort*, a genus of plants belonging to the *synnesia* class, and in the natural method ranking under the 49th order, composite.

LAPSE, in Ecclesiastical Law, a slip or omission of a patron to present a clerk to a benefice within six months of its being void; in which case, the benefice is said to be in lapse, or lapsed, and the right of presentation devolves to the ordinary.

LAPSED LEGACY, is where the legatee dies before the testator, or where a legacy is given upon a future contingency, and the legatee dies before the contingency happens.

LAP-SIDED, the state of a ship which is built in such a manner as to have one side heavier than the other, and by consequence to retain a constant heel or inclination towards the heaviest side; unless when she is brought upright by placing a greater quantity of the cargo or ballast on the other side.

LAQUEARIUS, a kind of master wrestler, or champion, among the ancients, who in one hand held a laqueus, i. e. a sort of snare, wherewith to embarrass and entangle his antagonist, and in the other a poniard to stab him.

LAQUERING, the laying on metals coloured or transparent varnishes, to produce the appearance of a different colour in the metal, or to preserve it from rust. Thus, laquered brass appears gilt; and tin is made yellow. Seed-lac is the chief composition for laquers, but turpentine makes a cheaper laquer.

To imitate Gilding on Brass, take one ounce of turmeric, add a drachm of saffron, and another of annatto, and add to these a pint of spirits of wine. Place the bottle in a moderate heat, shake it frequently for several days, and in the end you will procure a fine yellow. Add now three ounces of seed-lac, and when this is dissolved, strain off the mixture: or you may mix one ounce of turmeric root ground, half a drachm of dragon's

blood, and a pint of spirits of wine. Saffron is sometimes used to form the body of colour in this laquer, instead of the turmeric; it makes a warmer but more expensive yellow, and as turmeric has the advantage in forming a much stronger tinge in spirits of wine, it receives the preference. Aloes and gamboge are also sometimes used in laquers for brass: aloes are not necessary where turmeric or saffron is used; and the gamboge, though a strong juice in water, affords but a weak tinge in spirits of wine.

A Laquer for Tin, to imitate a Yellow Metal. Take one ounce of turmeric root, of dragon's blood two drachms, and one pint of spirits of wine; add a sufficient quantity of seed-lac.

A Laquer for Locks, &c. Seed-lac varnish alone, or with a little dragon's blood; or a compound varnish of equal parts of seed-lac and resin, with or without the dragon's blood.

A Gold-coloured Laquer for Gilding Leather. The gilt leather used for skreens, room-borders, &c. is leather covered with *auker* leaf, and laquered with the following composition: Take four pounds and a half of fine white resin, of common resin the same quantity, of gum-sandarach two pounds and a half, and of aloes two pounds; bruise those which are in great pieces, mix them together, put them into an earthen pot over a good charcoal fire, or any fire without flame. Melt all the ingredients, stirring them well with a spatula, that they may be thoroughly mixed, and prevented also from sticking to the bottom of the pot. When they are perfectly melted and mixed, add gradually to them seven parts of linseed oil, and stir the whole with the spatula. Make the liquid boil, stirring it all the time, to prevent the sediment from sticking to the bottom of the vessel. When the varnish is boiled seven or eight hours, add gradually half an ounce of litharge, or half an ounce of red-lead, and when they are dissolved, pass the varnish through a linen cloth, or flannel bag. The way of knowing when the varnish is sufficiently boiled, is by taking a little on some instrument, and if it draws out and is ropy, and sticks to the fingers, drying on them, it is prepared.

LAQUEUS, in Surgery, a kind of ligature, so contrived, that, when stretched by any weight, or the like, it draws up close. Its use is to extend broken or disjoined bones, to keep them in their places while they are set, and to bind the parts close together.

LARBOARD, a name given by seamen to the left side of a ship when the spectator's face is turned in the direction of the head.

LARBOARD-Tack, is when a ship is close hauled, with the wind blowing on her larboard side.

LARBOARD-Watch, a division of a ship's company on duty while the other is relieved from it. See the article **WATCH**.

LARBOWLINES, a cant term used by the boatswain's mates, implying the larboard watch.

LARCENY, or **THEFT**, by contraction for *latrocinium*, *latrocinium*, is distinguished by the law into two sorts: the one called *simple larceny*, or *plain theft*, unaccompanied with any other atrocious circumstance; and *mixed or compound larceny*, which also includes in it the aggravation of a taking from one's house or person. 1. Simple larceny, when it is the stealing of goods above the value of twelvepence, is called grand larceny; when of goods to that value, or under, is petty larceny: offences, which are considerably distinguished in their punishment, but not otherwise. See **THEFT**. 2. Mixed or compound larceny, is such as has all the properties of the former, but is accompanied with either one or both of the aggravations, of a taking from one's house or person.

LARD, the fat of swine, which differs in its situation from that of almost every other quadruped, as it covers the animal all over, and forms a thick, distinct, and continued layer betwixt the flesh and the skin, somewhat like the blubber in whales, applicable to various purposes both culinary and medicinal; and particularly to the composition of ointments. The usual mode of preparation is to melt it in a jar placed in a kettle of water, and in this state to boil it, and run it into bladders that have been cleaned with great care. The smaller the bladders are, the better the lard will keep. The fat which adheres to the parts connected with the intestines differs from common lard, and is preferably employed for the greasing of carriage wheels.

LARES, among the ancients, derived by Apulius De Deo Socratis, from *lar familiaris*, a kind of domestic genii, or divinities, worshipped in houses, and esteemed the guardians and protectors of families, supposed to reside more immediately in the chimney corner. The *lares* were distinguished from the *penates*, as the former were supposed to preside over house-keeping, the servants in families, and domestic affairs; and the latter were the protectors of the masters of families, their wives, and children. Accordingly, the *lares* were dressed in short succinct habits, to shew their readiness to serve; and they held a sort of cornucopia in their hands, as a signal of hospitality and good housekeeping. According to Ovid, there were generally two of them, who were sometimes represented with a dog at their feet. The *lares* are also called *penates*, and were worshipped under the figures of little marmosets, or images of wax, silver, or earthenware.

LARGE, a phrase applied to the wind when it crosses the line of a ship's course in a favourable direction, particularly on the beam or quarter; for instance, if a ship is steering west, the wind in any point of the compass to the eastward of the south or north, may be called large, unless it is directly east, and then it is said to be right aft.

SAILING Large, is therefore the act of advancing with a large wind, so as that the sheets are slackened and flowing, and the bowlines entirely disused. This phrase is generally opposed to sailing close-hauled, or with a scant wind, in which situation the sheets and bowlines are extended as much as possible.

LARMIER, in Architecture, a flat square member of the cornice below the cymasium, and jets out farthest; being so called from its use, which is to disperse the water, and cause it to fall at a distance from the wall, drop by drop, or as if by tears, the French word *larm* signifying a tear.

LARUS, the *Gull*, in Natural History, a genus of birds of the order anseres. They inhabit principally the northern climates, subsisting on carrion, and on fishes. Gmelin reckons fifteen species, and Latham nineteen.—*L. marinus*, is twenty-nine inches in length, and of the weight of five pounds. It is found in various parts of England, and on most of the northern coasts of Europe. It breeds in the most elevated cliffs, laying its eggs on heaps of dung deposited by various birds. It feeds principally on fishes, but sometimes attacks birds. The herring-gull, somewhat less than the former, frequents the same situations, and subsists, like that, chiefly upon fish. In the herring season it is seen watching the nets of the fishermen, and is daring enough frequently to seize its prey from the boats and nets.—The common gull, sixteen inches long, and about a pound in weight, breeds on the rocks and cliffs on the British coasts; and on the banks of the Thames, near its union with the sea, may be seen in immense numbers, picking up the worms and small fishes deposited by the tide. It will also follow the course of the plough over the fields, to pick up the insects and worms which are thrown up by it.—The black-cap, or pewit gull, breeds in the fens of Lincolnshire and Cambridgeshire, and, after the season of breeding is over, returns to the coasts. The old birds of this species are both rank and tough, but the young are eaten by many persons, and were formerly much admired for the table, taken so young as to be unable to fly.—The brown gull weighs about three pounds. It is more frequent in the cold than in the warmer latitudes, and is perhaps the most daring and fierce of all the species. In the Faro islands, lambs are stated to be often torn to pieces by it, and carried to its nest. On the island of Foula, however, it is said to be highly valued on account of its cunty to the eagle, which it attacks, and follows with the most animated hostility. Its feathers are thought by many to equal those of the goose.—The tarrock breeds in Scotland, and is found so far north as Spitzbergen. It is an attendant on the progress of whales and other large fishes, which drive the smaller inhabitants of the ocean into creeks and shallows, where the tarrocks suddenly dart on them, ensuring always an easy and full repast. The tarrock and its eggs are food for the Greenlanders, and of their skins are made caps and garments.

LARVA, in Natural History. The larva state of insects, in general, denotes caterpillars of all kinds. The caterpillar state is that through which every butterfly must pass before it arrives at its perfection and beauty.

LASHERS, are properly those ropes only which bind fast the tackles and the breeches of the ordnance, when they are haled or made fast within board.

LASHING, which denotes a piece of rope used to fasten or secure any moveable body in a ship, or about her masts, sails, and rigging, is chiefly used for binding up to the ship's side muskets, butts of water or beer, or pieces of timber to make spare top-masts.

LASKETS, small lines like hoops, sewed to the bonnets and drabblers of a ship, to lash or lace the bonnets to the courns, or the drabblers to the bonnets.

LASKING, is much the same with going larger or veering; that is, going with a quarterly wind. See the article **VEER**.

LASSITUDE, or **WEARINESS**, in Medicine, a morbid sensation, that comes on spontaneously, without any previous motion, exercise, or labour. This is a frequent symptom in acute distempers: it arises either from an increase of bulk, a diminution of proper evacuation, or too great a consumption of the fluids necessary to maintain the spring of the solids, or from a vitiated secretion of that juice.

LASTAGE, signifies the ballast or lading of a ship.

LATEEN SAIL, a triangular sail, frequently used by xebecs, polacres, fettees, and other vessels navigated in the Mediterranean sea.

L'ATELIER DE L'IMPRIMEUR, the *Printing Press*, is due to the innovating spirit of Monsieur Bode, who composed this asterism out of some distinct but unformed stars situated in the Milky Way, and Eastward of Canis Major's head: *Boundaries and Contents*: north, by Monoceros, east, by Canis Major; south, by Argo Navis; and west by Monoceros, Argo Navis, and Pyxis Nautica.

LATERAL EQUATION, is a term used by some old authors for what is now more commonly called a **SIMPLE EQUATION**.

LATH, in Building, a long, thin, and narrow slip of wood, nailed to the rafters of a roof or ceiling, in order to sustain the covering.

LATH-BRICKS, a particular sort of bricks, made in some parts of England, of twenty-two inches in length and six in breadth, which are used in the place of laths or spars, supported by pillars in casts, for the drying of malt. This is an excellent contrivance; for besides that they are not liable to fire, as the wooden laths are, they retain the heat vastly better; so that being once heated, a very small quantity of fire will keep them so.

LATHE, a very useful engine for the turning of wood, ivory, metals, and other materials. The invention of the lathe is very ancient. Diodorus Siculus says, the first who used it was a grandson of Dædalus, named Talus. Pliny ascribes it to Theodore of Samos, and mentions one Thericles, who rendered himself very famous by his dexterity in managing the lathe. With this instrument the ancients turned all kinds of vases, many whereof they enriched with figures and ornaments in basso relievo. The lathe is composed of two wooden cheeks or sides, parallel to the horizon, having a groove or opening between; perpendicular to these are two other pieces called puppets, made to slide between the cheeks, and to be fixed down to any point at pleasure. These have two points, between which the piece to be turned is sustained; the piece is turned round, backwards and forwards, by means of a string put round it, and fastened close to the end of a pliable pole, and underneath to a treadle or board moved with the foot. There is also a rest which bears up the tool, and keeps it steady. As it is the use and application of this instrument that makes the greatest part of the art of turning, we shall notice it hereafter under that word; at present we shall give a particular description of *Maudsley's Lathe*, as well as the manner of applying its various parts to one another.

Maudsley's LATHE, is shewn at large in the plate. A is the great wheel, with four grooves on the rim. This wheel is worked by a crank B and trundle C, in the common way, by a catgut string, which in going round the wheel passes also round a smaller wheel D, called the *mandrel*. This mandrel has on its circumference four grooves, of different diameters, for giving it different velocities, corresponding with the four grooves on the great wheel A. To make the same band suit, when applied to all the different grooves on the mandrel D,

the great wheel A can be raised or lowered by means of the screw *a*, and another at the end of the axle; and the connecting rod *e* can be lengthened or shortened by screwing the books at each end of it, further out of it, or more into it.

The end M of the mandrel D is pointed, and works in a hole in the end of a screw, passing through the standard E, fig. 1; the other end of the bearing F, fig. 2, is conical, and works in a conical socket in the standard F, 1; hence, by tightening up the screw in E, the conical end F may at any time be made to fit its socket: the puppet G has a cylindric hole through its top, to receive the polished pointed rod *d*, which is moved by the screw *e*, and fixed by the screw *f*; the whole puppet is fixed on the triangular prismatic bar H, by a clamp, fig. 8, the ends of which, *a* *b*, pass through holes, *b*, in the bottom of the puppet under the bar, and the hole is fixed by the screw *c* pressing against it: by this means, the puppet can be taken off the bar without first taking off the standard 1, as in the common lathes, and the triangular bar is found to be preferable to the double rectangular one in common use.

The rest J, in three pieces, is a similar contrivance; see figs. 3, 4, and 5.

Fig. 4, is a piece, the opening *a*, *b*, *c*, in which is laid upon the bar H, fig. 1; the four legs *dddd* of fig. 5, are then put up under the bar (into the recesses in fig. 4, which are made to receive them) so that the notches in *dddd* may be level with the top of fig. 4, the two beads *ef* in fig. 3, are then slid into the notches in the top of *dddd* fig. 4, to keep the whole together; the groove *i* receives a corresponding piece on *ef*, fig. 3, to keep it steady, the whole of fig. 3 has a metallic cover, to keep the chips out of the grooves.

It is plain, that by tightening the screw A in the bottom of fig. 4, the whole will be fixed and prevented from sliding along the bar H, and fig. 3, from sliding in a direction perpendicular to the bar; the piece *l*, fig. 3, on which the tool is laid, can be raised or lowered at pleasure, and fixed by the screw *m*.

On the end *n* of the spindle P, figs. 1 and 2, is screwed occasionally an *universal chuck* for holding any kind of work which is to be turned (see fig. 6). A is the female screw to receive the screw *n*, fig. 1; near the bottom of the screw A is another screw B B, which is prevented from moving endways by a collar in the middle of it fixed to the screw A: one end of the screw B B is cut *right-handed*, and the other *left-handed*; so that by turning the screw one way, the two nuts E F will recede from each other, or by turning it the contrary way, they will advance towards each other; the two nuts E F pass through an opening in C, and project beyond the same, carrying jaws like those of a vice, by which the subject to be turned is held.

For turning faces of wheels, hollow work, &c. where great accuracy is wanted, *Maudsley* has contrived an ingenious apparatus which he calls a *slide-tool*, represented by fig. 7, where E E E is the opening to receive the bar H, fig. 1, and is fixed by the clamp, fig. 8, as before described; the tool for cutting, &c. is fixed in the two holders *bb* by their screws; these holders are fastened to a sliding-plate *a*, which can be moved backwards and forwards by the screw *c*, causing the tool to advance or recede; fig. 9, represents the under side (turned upward) of the part A A, in which the screw *c* is seen fixed at each end, and the nut *d*, which is attached to the under side of the plate *a*, working upon it. When it is necessary, as in the turning of the inside of cones, &c. that the tool should not be parallel to the spindle P, the screw *e* and another similar one behind must be loosened, the tool set at the proper angle, and then be screwed tight again.

To make the piece A A move truly when it is turned round, there is a hole *f*, fig. 9, to receive a knob *g*, fig. 14, upon the plate B, which acts as a centre, and keeps it in its place; there are three holes on each side in the plate B, fig. 12, to put the screw *e* in at different times, thus giving the tool a greater range than the circular openings S S will admit. The part E E E E, represented separately and inverted in fig. 10, is of cast iron, and has a screw A working in it similar to fig. 9; the nut of this screw is attached to the bottom of the slide H, fig. 11, at *t*, which slides in the groove *i*, figs. 7 and 10; at one end of it is a box containing a screw *m*, hereafter described, and at the other is a frame of brass K K. Near the same end of the slide is a pin L, projecting above the plate, which is put

through an opening, J, in fig. 12, to steady it; while the other end C of fig. 12, is put through an opening M in the box D, fig. 12. In the part C is an oblique slit *ll* to receive a stub which projects from the bottom of the nut *n*, worked by the screw *m*, fig. 11; by this arrangement it is obvious that if the screw *m* is worked, the stub of the nut *n*, acting against the slide of the slit *ll* as an inclined plane, will move it backwards or forwards through the opening M; a metal cover *r*, fig. 14, is occasionally put over the opening for the nut *n* and screw *m*, to prevent the chips from falling in.

Near the four corners of the frame, fig. 12, are four small projections *o o o o*, with inclined sides, that fit into the four openings *p p p p* of figs. 13, and 7, these openings are cut out in two brass plates, screwed on at right angles to the plates B B, figs. 7, and 13; the ends *q q q q* of these plates slide between the edges of the frame K K and the box D, so as to prevent any other motion than a vertical one.

When this *slide-tool* is used, the puppet G is to be removed or pushed back further from F, and the tool is put upon the bar H, fig. 1, and fixed in the place of the rest J, by the clamp fig. 8; the distance from the centre *n* is adjusted by the screw A, which moves the slide, fig. 11, in the grooves *i*, figs. 7, and 10, with the whole apparatus upon it; by the screw *m*, figs. 7, and 11, as before described, the slide, fig. 12, may be moved in a direction perpendicular to the bar H, fig. 1; and its projections *o o* acting against the slits *p p*, figs. 7, and 13, as inclined planes, will raise or lower the plate B as is required.

The tool, which has been before fixed in the holders *b b*, can be set at the proper angle, by loosening the screw *e*, as previously described; and lastly, the tool with the holders and slider *a* can be advanced or withdrawn by working the screw *c*. The nuts of the screws *c*, and A, fig. 7, are not screwed fast to the sliding plates, but are held by two pins *t*, fig. 11, which fit into grooves *u*, fig. 10, in each side of the nut; by these means, the sliding plate can at any time be taken out by only unscrewing one of the brass sides from the groove *i*, without taking out the screw and nut. To make the grooves always fit their slides, the two pieces of brass *p y*, fig. 7, composing the sides of the groove, have elliptic holes for their screws *u*, so as to admit, when the screws are slackened, of being pushed inwards by the screws *u*, which work in a lump of metal cast with the part A A.

The larger lathes which this machinist uses in his manufactory, instead of being worked by the foot, as represented in fig. 1, are worked by hand; the wheel and fly-wheel which the men turn works by a strap on another wheel fixed to the ceiling, directly over it; on the axis of this wheel is a larger one, which turns another small wheel or pulley, fixed to the ceiling, directly over the mandrel of the lathe; and this last has on its axis a larger one which works the mandrel D, by a band of catgut. These latter wheels are fixed in a cast-iron frame, movable on a joint; and this frame has always a strong tendency to rise up from the action of a heavy weight; the rope from which, after passing over a pulley, is fastened to the frame; this weight not only serves to keep the mandrel-band tight, when applied to any of the grooves therein, but always makes the strap between the two wheels on the ceiling fit. As it is necessary that the workman should be able to stop his lathe, without the men stopping who are turning the great wheel, there are two pulleys or rollers, (on the axis of the wheel over the lathe,) for the strap coming from the other wheel on the ceiling; one of these pulleys, called the *dead pulley*, is fixed to the axis with which it turns, and the other which slips round it, is called the *live pulley*; these pulleys are put close to each other, so that by slipping the strap upon the *live pulley*, it will not turn the axis; but if slipped on the other it will turn with it; this is effected by a horizontal bar, with two upright pins in it, between which the strap passes. This bar is moved in such a direction as will throw the strap upon the *live pulley*, by means of a strong bell-spring; and in a contrary direction it is moved by a cord fastened to it, which passes over a pulley, and hangs down within reach of the workman's hand; to this cord is fastened a weight, heavy enough to counteract the bell-spring, and bring the strap up to the *dead pulley*, to turn the lathe; but when the weight is laid upon a little shelf, prepared for the purpose, the spring will act and stop it.

24.

There is some additional apparatus for cutting the teeth of wheels, in which the face of the mandrel D, fig. 1, has seventeen concentric circles upon it, each divided into a different number of equal parts, by small holes. There is a thin stop, *x*, fig. 1, which moves round on a screw, fixed in the standard F; this stop made of thin steel is so fixed, that when turned up, and its point inserted to any of the divisions of the mandrel, it has a sufficient spring to keep it there; the wheel to be cut is fastened, by means of a chuck, to the screw *n*, and after it has been turned, and brought to the proper shape, the rest J is taken away, and the slide-tool substituted; a square bar is then put into the two holders, *b b*, fig. 7; this bar has two branches for holding the ends of a spindle, near one end of which is a pulley, and, instead of the circular saw commonly used, at the other are four chisels, fixed perpendicularly into the spindle, for cutting out the teeth; the pulley is turned with the intervention of several wheels to augment the velocity by the same great wheel as the lathe, with 7300 revolutions per minute; the mandrel is then fixed by the stop *x*, fig. 1, and the cutter advanced towards the wheel by the screw *c*, fig. 7. When it has cut that tooth, the cutter is withdrawn, and the mandrel turned to another division, and another tooth is cut again as before. At that part of the frame of the cutting spindle where the bar, fixed in the holders of the slide-tool, connects with the two branches, there is a joint, by which the cutting-spindle can be placed in an inclining position, for cutting oblique teeth, like those which work with an endless screw. The great velocity with which this spindle turns, soon generates, by friction and resistance, a degree of heat sufficient to expand it very sensibly; but this ingenious mechanist has judiciously compensated for it in his construction, by making the spindle so short as to play loosely in its sockets at the commencement of the motion; but after a few seconds the expansion causes the whole to fit together as it ought to do, and the work of cutting proceeds with accuracy, safety, and despatch.

As an improvement on the common lathe, Mr. Williamson, of Union-street, Lambeth, from many years' experience, has been induced to turn his attention to some mode of decreasing the friction, and lightening the labour. This he has at length accomplished by a simple addition to the machine that we shall immediately describe, first saying a few words on the construction of the common lathe.

The diameter of the wheel is about three feet; of the pulley, four or five inches; the line introduced under the one and over the other, commonly touches about $\frac{1}{4}$ of the pulley; and, therefore, to cause any body to revolve, whose diameter is the same as that of the pulley, or larger, a very thick line, about three-eighths of an inch diameter, or a line very tight, must be used, which in either case increases the friction, and of course materially increases the labour.

Now, the way in which Williamson works his lathe, so as to decrease the friction and lighten the labour, is by carrying the line over a second pulley, working on centres, and so placed as to leave the workman the power of tightening the line with facility, by means of a weight, according to the work he is engaged on. With this little addition, the workman uses a line only one-eleventh of an inch thick, which, applied according to the above figure, will carry, or cause to revolve, upon a nine-inch pulley, the nave of a waggon

7 D

wheel, sixteen inches diameter, and eighteen inches long, (the dimensions in rough.) We mention this, to shew that it is suited to all sorts of work that can be done by the turner, and, in fact, enables him to do much heavier work than his strength would permit in the ordinary way.

Its advantages appear to be:—1. Decrease of friction. 2. That the same line can be employed for all the various speeds that are necessary. 3. That the effect of the various temperatures of the atmosphere upon the line is of no consequence, as, by means of the weight, it can be made to accommodate itself to the different changes. With catgut, which is generally used, this change of atmosphere, in the ordinary way, is found to occasion not only the frequent destruction of lines, but a great waste of time in repairing them.

The turner has generally upon his mandrel various-sized pulleys; yet it is no uncommon thing to find the line too slack upon one pulley, and too tight upon the next, when of necessity it must be dragged upon the larger, where it frequently breaks immediately, especially if the atmosphere is becoming more dense. Upon the same pulley the line can be used slack for small articles, and as tight as it may be found necessary for larger articles, by decreasing or increasing the weight, as occasion may require.

Description of the Drawing.—A, the wheel; B, the pulley; C, the additional pulley for the line to revolve on. D, the frame in which the additional pulley C works on centres; E, a joint on which the frame D works, to tighten the string by means of the weight H; F, screw centres for the pulley C; G G, pulleys for communication between the weight H and the frame D; H, the weight; I, section of the wheel A; K, section of the pulley B; L, centres and edge of the additional pulley C; M, a pin, on which, when the ring at the end of the line N is hung, the lathe is stopped.

Shortly after this account of Mr. Williamson's improvement made its appearance in the *Mechanic's Magazine*, a correspondent in that publication remarked, that this improvement, though extremely valuable, was susceptible of considerable simplification; and at the same time presented the following drawings of a plan, as calculated to prevent the line from chafing, and likewise obviate the necessity of changing the line for heavy work, as in the original plan.

Fig. 1 is the appearance of the lathe endwise; C represents one of two pieces, which are fixed to the back-bed of the lathe; F is a lever, moveable on the centre O, which lever has a piece cut out of the end, to admit the extra pulley D, which

Fig. 1.

Fig. 2.

must, to allow the band to pass without rubbing, be placed so as to stand in winding with the pulley on the mandrel, as shewn

by d, fig. 2; the lever F is furnished with hooks, on which the weight G is hung, according to the nature of the work. It would improve the plan, if the grooves in the mandrel-pulley, instead of being angular, were turned rather flat at the bottom. Fig. 2 will be readily understood, as the same letters denote the same parts as in fig. 1. A A are beds of the lathe; C, the mandrel-pulley; B, the large wheel.

LATION, is sometimes used for translation or change of place.

LATITUDE, in Geography or Navigation, is the distance of a place from the equator, reckoned on an arch of the meridian, intercepted between its zenith and the equator.

North Latitude, is that which falls in the northern hemisphere; viz. between the equator and the north pole.

South Latitude, is that which falls in the southern hemisphere, or between the equator and south pole.

Parallels of Latitude, are small circles of the sphere supposed parallel to the equator; and are thus called because they shew the latitude of places by their intersection with the meridians, all places falling under the same circle being in the same latitude. The quadrant, or meridian, intercepted between the equator and either pole, is divided into ninety degrees, and numbered both ways from the equator to the poles; and the latitude of any place is equal to the measure of the arch intercepted between the equator and that place, and which is said to be north or south, according as it is situated towards the north or south pole. The latitude of a place, and the elevation of the pole above the horizon of that place, are terms frequently used indifferently the one for the other, being in fact equal to each other. To comprehend with precision the definitions now laid down, we shall have recourse to a diagram.

The circle

MON represents

the horizon, in the centre

of which,

and on the

earth, an ob-

server A is

placed; B C D,

B' C' D' are por-

tions of circles

which the hea-

venly bodies

seem to de-

scribe round

the celestial

pole (P), when we fancy they rise in the east and set in the west. Those whose distance from the pole is less than the arc P N, which marks the elevation of this point above the horizon, appear to describe entire circles, such as G K I H. N is the north point of the horizon; M the south; and consequently M N is the meridian line. The semi circle M Z N, the plane of which is supposed to be perpendicular to the horizon M E N O, and which passes through the points M N, is the celestial meridian, which divides the arcs B C D, B' C' D', into two equal parts in the points C, C'. The point E is the east point of the horizon, and the point O the west point:—the heavenly bodies seem to move from E to O by transversing the meridian M Z N, which marks the middle of their course.

If we conceive the terrestrial globe we inhabit to be insulated, our station in the horizon and the axis of the earth being similar as in the diagram, it is evident that the horizon turning with us during the rotation of the globe, advances successively towards the stars situated in the direction of its motion, which consequently seems to be moving in an opposite direction to approach us. The plane M Z N of the meridian M N, perpendicular to the horizontal plane E N O M, turns also with this latter, and directs itself successively towards the same stars which are then in the middle of the course which they seem to describe above the horizon. When the western edge of the horizon touches a star, it appears to set, and ceases to be visible till the motion of the earth brings the eastern edge of the horizon towards it; because, during this interval, the visual rays which touch the earth pass above the star. This illustration accounts, in the most plain and simple manner, for the

daily appearance and disappearance of the celestial bodies, by which circumstance the sun produces the alternation of day and night. All the motions alluded to, in the preceding definitions, are measured by their angles only, without any consideration of their absolute distances.

The *Zenith* is indicated by Z, being perpendicularly over the observer's head; and the *Nadir* is directly opposite.

If we suppose the plane B'C'D' to be perpendicular to the axis of rotation, which passes from P through A, till it meets in the opposite hemisphere a point coinciding with P, this plane B'C'D' will indicate the equator, all the points of which are at an equal distance from the poles P, P'. It follows from this equality, that, to a spectator placed on the equator, the poles are in the horizon; but as he advances towards either pole, it becomes elevated, while the other is depressed. And the angle P A N, which measures the elevation of the pole above the horizon, is equal to that which measures the angular distance of a place from the equator, estimated in the direction of the meridian. Also the height at which the equator appears above the horizon, is the complement of the angle Z A C*; for Z A N, C A P, being respectively right angles, if we subtract the common angle Z A P, the remainder Z A C' = P A N. Hence if we suppose Z to be London $51^{\circ} 31'$ from the equator C, the elevation of the pole is also $51^{\circ} 31'$. As soon then as the height of the pole above the horizon can be determined for any place, the angular distance of this place from the equator is known, or the number of parts of the meridian intercepted between this place and the horizon.

The circumpolar stars, which never set in those places where one of the poles is elevated above the horizon, determine this immediately; for since they appear to describe circles round the celestial pole, they are equally distant from it in every direction, and as they pass twice over the meridian during the diurnal revolution of the earth, namely, once above the pole, and once below it, if we measure their angular elevation at each of these positions, and take the mean of these two results, we shall obtain the elevation of the pole.

Let A be an observer on the earth, and let G H I K be the circle which a star describes round the point P; then by measuring the angle I A N when the star is on the meridian above the pole, and also the angle G A N when the same star is on the meridian below the pole; the angles I A P, G A P being equal, the angle P A N is the mean between I A N and G A N, and is equal, consequently, to half their sum. Moreover, if we take half the difference I A G of the angles I A N and G A N, measured between the star and horizon, we shall obtain the angle I A P, which will give the angular distance between the observed star and the celestial pole.

Thus, by measuring, for example, at London, during a long winter's night, the two meridian heights of the polar star (*a Uree Minoris*, having $88^{\circ} 20' 49''$ declin. N.) we find that (*Ann.* 1820,)

When it passes above the pole its altitude measures.....	$53^{\circ} 10' 11''$
And when it passes below the pole, it measures.....	$49^{\circ} 51' 49''$

The sum of which is	$103^{\circ} 02' 00''$
And their half.....	$51^{\circ} 31' 00''$

Which will be the altitude of the pole above the horizon of London, or the distance of this city from the equator.

If, on the contrary, we subtract $49^{\circ} 51' 49''$ from $53^{\circ} 10' 11''$, we shall find for their difference $3^{\circ} 18' 22''$, of which the half $1^{\circ} 39' 11''$ will give the distance of the polar star from the pole (in 1820), which we thus find does not exactly occupy this point, but is yet very near to it.

The stars enable us to determine another position relative to any place where our former observation may have been made, namely, the *longitude* of that place: between the passage of the same star over any two meridians, a period of time elapses which is to the whole time of rotation as the angle made by these meridians is to two right angles; so that if the first interval can be measured, to compare it with the second, we may deduce the angle which the two meridians make with each

other. This could be done, if we could indicate by a signal visible at the same time to the places under the two meridians the moment when a star appears on one of the meridians; because this instant being marked, a well-regulated watch would give the time which elapses between this transit and that of the same star over the other meridian.

If, for example, two observers, one at Portsmouth, R. N. Academy, and the other at Plymouth Garrison, having agreed to determine on the same day, the transit of the same star over the meridian of the place they inhabit, and that a signal given the moment when the star passes the meridian of Portsmouth Academy, could be visible at Plymouth garrison, about 12 minutes 6 seconds would elapse before the star would pass the meridian of Plymouth; and this interval being nearly the 120th part of the diurnal revolution of the earth, it follows that the plane of the meridian which passes over the Royal Navy Academy at Portsmouth, makes with that of the plane of the meridian which passes over the garrison of Plymouth, an angle which is nearly the 120th part of four right angles, or the measure of $3^{\circ} 1' 23''$ according to actual observation. If for Portsmouth and Plymouth we substitute St. Paul's, London, and Sherburn Castle, the premises will give us one 360th part of the earth's diurnal revolution, or $4'$ in time = 1° of the equinoctial. This second position of a place being thus determined, fixes its exact situation; for Sherburn, for instance, being, we shall say, in the same latitude with London, and $4'$ later than it, its longitude is 1° west. So also Plymouth is $3^{\circ} 1' 23''$ west of Portsmouth.—*From Dr. Jamieson's CELESTIAL ATLAS.*

LATITUDE, in Astronomy, as of a star or planet, is its distance from the ecliptic, being an arch of latitude of a circle of latitude, reckoned from the ecliptic towards the poles, either north or south. Hence, the astronomical latitude is quite different from the geographical, the former measuring from the ecliptic, and the latter from the equator, so that this latter answers to the declination in astronomy, which measures from the equinoctial. The sun has no latitude, being always in the ecliptic, but all the stars have their several latitudes, and the planets are continually changing their latitudes, sometimes north and sometimes south, crossing the ecliptic from the one side to the other; the points, in which they cross the ecliptic, being called the nodes of the planet, and in these points it is that they can pass over the face of the sun or behind his body, viz. when they come both to this point of the ecliptic at the same time.

Circle of LATITUDE, is a great circle passing through the poles of the ecliptic, and consequently perpendicular to it, like as the meridians are perpendicular to the equator, and pass through its poles.

LATITUDE of the Moon, North ascending, is when she proceeds from the ascending node towards her northern limit or greatest elongation.

LATITUDE, North descending, is when the moon returns from her northern limits towards the descending node.—**LATITUDE, South descending**, is when she proceeds from the descending node towards her southern limit.—**LATITUDE, South ascending**, is when she returns from her southern limit towards her ascending node: and the same is to be understood of the other planets.

Heliocentric LATITUDE, of a Planet, is its latitude or distance from the ecliptic, such as it would appear from the sun. This, when the planet comes to the same point of its orbit, is always the same, or unchangeable.—**Geocentric LATITUDE**, of a Planet, is its latitude as seen from the earth. This, though the planet be in the same point of its orbit, is not always the same, but alters according to the position of the earth in respect to the planet. The latitude of a star is altered only by the aberration of light, and the secular variation of latitude.

Difference of LATITUDE, is an arc of the meridian, or the nearest distance between the parallels of latitude of two places. When the two latitudes are of the same name, either both north or both south, subtract the less latitude from the greater, to give the difference of latitude; but if they are of different names, then their sum will be the difference of latitude.

LATTEN, iron plates tinned over, of which tea-canisters are made. See **TINNING**.

LAUGHTER, an affection peculiar to mankind, occasioned

* In referring to this diagram, the reader will understand that a right line is supposed to connect Z A, P A, C A, &c.

by sneezing that tickles the funny. In laughter, the eyebrows are raised about the middle, and drawn down next to the nose; the eyes are almost shut; the mouth opens and shows the teeth, the corners of the mouth being drawn back and raised up; the cheeks seem puffed up, and almost hide the eyes; the face is usually red; the nostrils are open; and the eye wet.

LAUNCH, a peculiar kind of boat. The principal superiority of the launch to the long boat, consists in being by its construction much fitter to undertake the cable, which is a very necessary employment in the harbours of the Levant sea, where the cables of different ships are fastened across each other; and frequently render this exercise extremely necessary.

LAUNCH, is also the movement by which a ship or boat descends into the water; hence, to **LAUNCH**.

To facilitate the operation of launching, and prevent any interruption therein, the ship is supported with two strong platforms built with a gradual inclination to the water on the opposite sides of her keel, to which they are parallel. Upon the surface of this declivity are placed two corresponding ranges of planks, which compose the base of a frame called the cradle, whose upper part envelops the ship's bottom, wherein it is securely attached. Thus the lower surface of the cradle conforming exactly to that of the frame below, lies flat upon it, lengthways, under the opposite side of the ship's bottom, and as the former is intended to slide downwards upon the latter, carrying the ship along with it, the planes or faces of both are well daubed with soap and tallow.

The necessary preparations for the launch being made, all the blocks and wedges by which the ship was formerly supported are driven out from under her keel, till her whole weight gradually subsides upon her platform, above described, which are accordingly called the Ways. The shores and stanchions by which she is retained upon the stocks till the period arrives for launching, are at length cut away, and the screws applied to move her if necessary. The motion usually begins on the instant when the shores are cut, and the ship slides downwards along the ways, which are generally prolonged under the surface of the water to a sufficient depth to float her as soon as she arrives at the furthest end thereof.

When a ship is to be launched, the ensign, jack, and pendant are always hoisted, the last being displayed from a shaft erected in the middle of the ship. Ships of the first rate are commonly constructed in dry docks, and afterwards floated out by throwing open the flood-gates, and suffering the tide to enter, as soon as they are finished.

LAUNCH Ho, is the order to let go the top-rope after the top-mast is hided.

LAUNDER, in Mineralogy, a name given in Devonshire, and other places, to a long and shallow trough which receives the powdered ore after it comes out of the box or coffer, which is a sort of mortar, in which it is powdered with iron pestles. The powdered ore, which is washed into the launder by the water from the coffer, is always finest nearest the grate, and coarser all the way down.

LAURUS NOBILIS. BAY TREE. Leaves and Berries.—In distillation with water, the leaves of bay yield a small quantity of very fragrant essential oil; with rectified spirit, they afford a moderately warm pungent extract. The berries yield a larger quantity of essential oil: they discover likewise a degree of unctuousity in the mouth; give out to the press an almost insipid fluid oil; and on being boiled in water, a thicker butyraceous one, of a yellowish-green colour, impregnated with the flavour of the berry. An infusion of the leaves is sometimes drunk as tea; and the essential oil of the berries may be given from one to five or six drops on sugar, or dissolved by means of mucilage, or in spirit of wine.

LAURUS HANNYFRAS. SASSAPARILLA TREE. Bark.—Its medical character was formerly held in great estimation; and its sensillike qualities, which are stronger than any of the woods, may have probably contributed to establish the opinion so generally entertained of its utility in many inveterate diseases; for, soon after its introduction into Europe, it was sold at a very high price, and its virtues were extolled in publications professedly written on the subject. It is now, however, thought to be of very little importance, and seldom employed but in

conjunction with other medicines of a more powerful nature. Dr. Cullen found, that a watery infusion of it laid upon warm and pretty largely, was very effectual in promoting sweat; but he adds, "to what particular purpose this sweating was applicable, I have not been able to determine." In some constitutions, sassafras, by its extreme fragrance, is said to produce headache; to deprive it of this effect, the decoction ought to be employed.

LAURUS. Bay-tree. a genus of the *eucandria monogynia* class and order of plants. Natural order of *holocarpeæ*. There are 32 species. This genus consists of trees or shrubs; leaves mostly entire, in a few nearly opposite, commonly perennial, as in most trees of the torrid zone. *L. nobilis*, common sweet bay, grows from twenty to thirty feet in height; it has large evergreen leaves, of a firm texture, with an agreeable smell, and an aromatic bitterish taste; flowers dioecious, or male and female on different trees, in racemes shorter than the leaves, of an herbaceous colour; corollas four-petalled in the male flowers; stamens from eight to twelve; berry superior, of a dark purple colour, almost black; it is a native of the southern parts of Europe and Asia. *L. persea*, alligator, or avocado pear of the West Indies, is about thirty feet in height; the fruit is the size of one of our biggest pears, enclosing a large seed with two lobes. It is held in great esteem in the West Indies; the pulp is of a pretty firm consistence, and has a delicate rich flavour. *L. cinnamomum*, or cinnamon-tree, is a native of Ceylon. It has a large root, and divides into several branches, covered with a bark, which on the outer side is of a grayish brown, and on the inside has a reddish cast. The body of the tree, which grows to the height of twenty or thirty feet, is covered, as well as its very numerous branches, with a bark, which at first is green and afterwards red. The leaf is longer and narrower than the common bay-tree; and it is three-nerved, the nerves vanishing towards the top. The flowers are small and white, and grow in large branches at the extremity of the branches. The fruit is shaped like an acorn, but is not so large.

LAVA, the production of *Ætna*, *Vesuvius*, *Pecla*, and other volcanoes, is of a grayish colour passing to green: it is spotted externally, and occurs porous, carious, or vesicular. Its lustre is vitreous, more or less glistening. It is moderately hard, brittle, easily frangible, and light. It generally attracts strongly the magnetic needle. It is easily fusible into a black compact glass. It frequently encloses other fossils, especially crystals of felspar, angite, hornblende, and leucite. See **VOLCANOE**.

LAVENDER LEAVES. Lavender has been an official plant for a considerable time, though we have no certain accounts of it given by the ancients. Its medical virtue resides in the essential oil, which is supposed to be a gentle corroborant and stimulant, of the aromatic kind; and is recommended in nervous debilities, and various affections proceeding from a want of energy in the animal functions.

LAYING THE LAND, the state of motion which increases the distance from the coast, so as to make it appear lower and smaller; a circumstance which evidently arises from the intervening convexity of the surface of the sea. It is used in contradistinction to raising the land, which is produced by the opposite motion of approach towards it.

To **LAY-IN off a Yard**, to come from the yard-arms towards the mast, so as to quit it at the rigging. **LAYING out on a Yard**, is to go out towards the yard-arms.

LAY-MAN, among Painters, a small statue, whose joints are so formed, that it may be put into any attitude, for the purpose of adjusting the drapery of figures.

LAZARETTO, a building, or vessel, fitted up and appointed for the performance of quarantine, in which all persons are confined who are suspected to have come from places infected with the plague.

LAZULITE, in Mineralogy, is of a deep smalt blue; it occurs disseminated in fine grains, or masses, of the size of a hazel-nut.

LEAD, a white metal of a considerably blue tinge, very soft and flexible, not very tenacious, and consequently incapable of being drawn into fine wire, though it is easily extended into thin plates under the hammer. Its specific gravity is 11.35. It melts at 612 deg. In a strong heat it boils, and emits fumes;

during which time, if exposed to the air, its oxidation proceeds with considerable rapidity. Lead is brittle at the time of congelation. In this state it may be broken to pieces with a hammer, and the crystallization of its internal parts will exhibit an arrangement in parallel lines. Lead is not much altered by exposure to air or water, though the brightness of its surface, when cut or scraped, very soon goes off. It is probable that a thin stratum of oxide is formed on the surface, which defends the rest of the metal from corrosion. Most of the acids attack lead. The sulphuric does not act upon it, unless it be concentrated and boiling. Nitric acid acts strongly on lead. Muriatic acid acts directly on lead by heat, oxidizing it, and dissolving part of its oxide. The acetic acid dissolves lead and its oxides, though probably the access of air may be necessary to the solution of the metal itself in this acid. White lead, or ceruse, is made by rolling leaden plates spirally up, so as to leave the space of about an inch between each coil, and placing them vertically in earthen pots, at the bottom of which is some good vinegar. This, like all the preparations of lead, is a deadly poison. The common sugar of lead is an acetate; and Goulard's extract, made by boiling litharge in vinegar, a subacetate. The power of this salt, as a coagulator of mucus, is superior to the other. If a bit of zinc be suspended by brass or iron wire, or a thread, in a mixture of water and the acetate of lead, the lead will be revived, and form an arbor Saturni. Oils dissolve the oxide of lead, and become thick and consistent; in which state they are used as the bases of plasters, cements for water-works, paints, &c. Sulphur readily dissolves lead in the dry way, and produces a brittle compound, of a deep grey colour and brilliant appearance, which is much less fusible than lead itself. Lead unites with most of the metals. Two parts of lead, and one of tin, form an alloy more fusible than either metal alone: this is the solder of the plumbers. Bismuth combines readily with lead, and affords a metal of a fine close grain, but very brittle. A mixture of eight parts bismuth, five lead, and three tin, will melt in a heat which is not sufficient to cause water to boil. All the oxides of lead are easily revived with heat and carbon. Oxygen and lead combine together in different proportions. If the nitre of lead be dissolved in a precipitation produced by potash, the precipitate, when dried, will become the yellow protoxide. If it be somewhat vitrified, it constitutes litharge; and combined with carbonic acid, it becomes white lead or ceruse. This protoxide forms the pigment massicot. Massicot exposed for about 48 hours to a great heat, becomes red lead, or minium. Salts of lead have the peroxide for their base. They yield, when placed on charcoal by the blow-pipe, a button of lead. They dissolve in water, and yield a colourless solution of an astringent sweetish taste. Lead, alloyed with an equal weight of tin, ceases to be acted upon by vinegar. Acetate and subacetate of lead have a good effect, as external applications, for inflamed surfaces, burns, scrofulous sores, and as eye washes. Lead taken internally is very injurious: hence the diseases to which painters are liable. Litharge, dissolved in wines, to give them a sweet taste, is very mischievous. Sulphuretted hydrogen will cause it to throw down a black precipitate.

LEAD, Black. See **BLACK LEAD**.

LEAD, SUGAR OF. A salt, denominated from its composition, by modern chemists, acetate of lead, is much used in calico printing and other manufactures.

LEAD, Ores of. Ores of lead occur in great abundance in almost every part of the world. They are generally in veins; sometimes in siliceous rocks, sometimes in calcareous rocks. Nearly all the lead in commerce is obtained from galena, which is a compound of sulphur and lead.

LEAD, an instrument for discovering the depth of water; it is composed of a large piece of lead, from seven to eleven pounds weight, and is attached, by means of a strop, to a long line called the lead-line, which is marked at certain distances to ascertain the fathoms.

To Heave the LEAD, is to throw it into the sea in a manner calculated to produce the desired effect. **Deep-Sea LEAD,** a lead of a larger size, being from 25 to 30 pounds weight, and attached to a much longer line than the former, which is called a hand-lead.

LEADSMAN, the man who heaves the lead.

LEADING WIND, a free or fair wind, and is used in contradistinction to a scant wind.

LEAGUE, a measure of length, containing more or less geometrical paces, according to the different usages and customs of countries. A league at sea contains three thousand geometrical paces, or three English miles. The French league sometimes contains the same measure, and in some parts of France it consists of three thousand five hundred paces: the mean or common league, consists of two thousand four hundred paces, and the little league of two thousand.—Seventeen Spanish leagues make a degree, or sixty-nine and a half English statute miles. The Dutch and German leagues contain each four geographical miles. The Persian leagues are equal to four Italian miles, pretty near to what Herodotus calls the length of the Persian parasang, which contains thirty stadia, eight of which make a mile.

LEAK, a chink or breach in the deck, sides, or bottom of a ship, through which the water passes into her hull. When a leak first commences, a vessel is said to have sprung a leak.

LEAKAGE, is the quantity which runs out of a cask through a leak.

LEAKY, the state of a ship when abounding with leaks; also of a cask which suffers the liquor within it to run out.

LEASE, a conveyance of lands or tenements generally in consideration of rent or other annual recompense for life, for years, or at will, but always for a shorter term than the lessor has in the premises, otherwise it partakes more of the nature of an assignment.

All leases of lands, except leases not exceeding three years, must be made in writing, and signed by the parties themselves, or their agents duly authorized, otherwise they will operate only as leases of will. If a lease is but for half a year, or a quarter, or less time, the lessee is respected as a tenant for years. To constitute a good lease, there must be a lessor not restrained from making the lease to the extent for which it is granted; a lessee capable of receiving it; and the interest demised must be a demisable interest, and be sufficiently and properly described. If it is for years, it must have a certain commencement and termination; it is to have all the usual ceremonies, as sealing, delivery, &c. and there must be an acceptance of the thing demised.

Leases for life must not be made to commence at a future day, and there must be a livery of seisin. They must now be stamped as a lease, to be valid; and any form of writing will constitute a lease, provided it contains words of present demise, or actual letting; but if it be only an agreement to let, it conveys no immediate title in law, but only an equitable right to have a lease, or to sue at law for not making one. If a lease is made to one for years, and at the same time to another for a longer time, the last lease is not void, but shall take effect after the first expires. A tenant for life can in general only grant a lease to insure during his life; but sometimes a power is annexed to such an estate to grant leases for a specified time, and under particular limitations, all which must be strictly complied with, or the lease is void. An infant may make a lease; but may set it aside when come of age, and the court of chancery is empowered to grant leases for idiots, lunatics, infants, and married women.

The rent must be reserved to the executor or the heir of the lessor, according as his estate is real or personal. Lessees are bound to repair, unless the contrary is specified, and although if the house is burnt by accident they are not bound to rebuild yet they must, if the fire be by negligence; and if there is a covenant to pay rent, and a covenant to repair, except in case of fire, yet rent is payable, although the house is not rebuilt by the landlord. If there is a covenant not to assign, lease, or under-let, without license of the landlord, the tenant cannot even grant an under lease. Upon a lease at will, six months' notice to quit must generally be given by either party, to terminate on the same day in the year when the lease commenced. Leases made by spiritual persons of their church lands, must be conformable to the statute called the Enabling and Disabling statutes. The tenant may, at the trial of an ejectment, insist upon his notice to quit being sufficient, although he made no objection when it was served.

LEATHIER, The Manufacture of. The leather tanned in England consists of butts, hides, and skins. Butts are manu-
7 E

factured out of the strongest skins of oxen. The hides are laid in heaps two days in summer, and six in winter; they are then hung up on poles, in a close room or smoke-house, exposed to the heat of a smouldering fire of wet tan. Afterwards the hair is scraped off, and they are thrown into a pool of water, and again spread on a wooden beam and carefully scrubbed. They are now put into pits of strong bark ooze; again into a strong solution of vitriolic acid; next they are spread in a pit with ground bark strewed between each, where they lie six weeks, and the decayed bark and liquor being drawn out of the pit, it will precipitate. Isinglass is used for this purpose, being entirely composed of gelatine. And here it may be observed, that this is the mode of ascertaining the quantity of tanning principle in any vegetable substance, and consequently how far they may be used as a substance for hard oak. The hides being prepared in the usual way, are immersed for some hours in a weak tanning lixivium of two degrees' strength. To obtain this, the latter portions of the infusions are set apart, or else some of that which has been partly exhausted by use in tanning. The hides are then to be put into a stronger lixivium, where in a few days they will be brought to the same degree of saturation with the liquor in which they are immersed. The strength of the liquor will thus be considerably diminished, and must therefore be renewed. When the hides are by this means perfectly tanned, they are to be removed, and slowly dried in the shade. The length of time necessary to tan leather completely, according to the old process, is a great inconvenience; and there is no doubt that it may be much shortened by following the new method; but the leather so tanned has not been so durable as that which has been formed by the slower process.

Sir H. Davy, in treating "on the Constituent Parts of Astringent Vegetables," thus speaks of tanning:—In considering the relation of the different facts that have been detailed, to the processes of tanning and of leather-making, it will appear sufficiently evident, that when skin is tanned in astringent infusions that contain, as well as tannin, extractive matters, portions of these matters enter with the tannin, into chemical combination with the skin. In no case is there any reason to believe that gallic acid is absorbed in this process; and M. Seguin's ingenious theory, of the agency of this substance, in producing the de-oxygenation of skin, seems supported by no proofs. Even in the formation of glue from skin, there is no evidence which ought to induce us to suppose that it loses a portion of oxygen; and the effect appears to be owing merely to the separation of the gelatine from the small quantity of albumen with which it was combined in the organized form, by the solvent powers of water. The different qualities of leather made with the same kind of skin, seem to depend very much upon the different quantities of extractive matter it contains. The leather obtained by means of infusion of galls, is generally found harder, and more liable to crack, than the leather obtained from the infusion of barks; and in all cases it contains a much larger proportion of tannin, and a smaller proportion of extractive matter. When skin is very slowly tanned in weak solutions of the barks, or caoutchouc, it combines with a considerable proportion of extractive matter; and in these cases, though the increase of weight of the skin is comparatively small, yet it is rendered perfectly insoluble in water, and is found soft, and at the same time strong. The saturated astringent infusions of barks contain much less extractive matter, in proportion to their tannin, than the weak infusions; and when skin is quickly tanned in them, common experience shews that it produces leather less durable than the leather slowly formed. Besides, in the case of quick tanning by means of infusions of barks, a quantity of vegetable extractive matter is lost to the manufacturer, which might have been made to enter into the composition of his leather. These observations shew, that there is some foundation for the vulgar opinion of workmen, concerning what is technically called the *feeding* of leather in the slow method of tanning; and though the processes of the art may in some cases be protracted for an unnecessary length of time, yet, in general, they appear to have arrived, in consequence of repeated practical experiments, at a degree of perfection which cannot be very far extended by means of any elucidations of theory that have as yet been known.

Currying. The art of currying consists in rendering tanned skins supple, of uniform density, and impregnating them with oil, so as to render them in a great degree impervious to water. The strong and thick hides are employed for making the soles of boots and shoes, and these are rendered fit for their several purposes by the shoemakers after they are tanned: but such skins as are intended for the upper leathers and quarters of shoes, for the legs of boots, for coach and harness leather, saddles, and other things, must be subject to the process of currying. These skins, after coming from the tannors, have fleshy fibres on them. They are well soaked in common water, then taken out, and stretched upon a very even wooden horse; where with a paring knife all the superfluous flesh is scraped off, and they are again put into a pit or vessel to soak. After the *soaking* is completed, the currier takes them again out of the water, and having stretched them out, presses them with his feet, or a flat stone fixed in a handle, to make them more supple, and to press out all the filth that the leather may have acquired in tanning, and also the water it has absorbed in soaking. The skins are next to be *oiled*, to render them pliant and impervious to wet. After they are half dried, they are laid upon tables, and first the grain side of the leather is rubbed over with a mixture of fish-oil and tallow; then the *flesh side* is impregnated with a large proportion of oil. After having been hung up a sufficient time to dry, they are taken down and rubbed, pressed, and folded, and then spread out, when they are rolled with considerable pressure upon both sides with a fluted board fastened to the operator's hand by a strap; by this means, and by repeating the rolling, a grain is given to the leather. After the skins are curried, it may be required to colour them. The colours usually given to them are black, white, red, green, yellow, &c. If the skins are to be blacked, the process varies according to the side of the skin to be coloured. Leather that is to be blacked on the flesh side, which is the case with most of the finer leather intended for shoes and boots, is coloured with a mixture of lamp black, oil, and tallow rubbed into the leather. And what is to be coloured on the grain side is done over with chamber-lice, and then with a solution of sulphate of iron, which turns it black.

Water-proof Leather. To render leather water-proof, the following method is adopted: Take a small pipkin or earthen vessel, and put in it three ounces of spermaceti, to be melted over a slow fire; then take three-quarters of an ounce of caoutchouc, or Indian rubber, cut into thin slices; and the spermaceti will completely dissolve this substance. Add eight ounces of tallow, two ounces of hog's lard, and four ounces of amber varnish. The boots or shoes must be rendered dry and warm, and this cement well rubbed in, three or four times, with a brush.

Morocco Leather is made of the skins of goats, tanned and dyed in a peculiar manner by the Turks. This process, originally invented in the kingdom of Morocco, has given rise to the name of Morocco leather. *English Morocco leather*, used so largely for coach-linings, pocket-books, and the best kind of book-binding, is prepared from sheep-skins.

Shagreen is a sort of rough leather, prepared from the skin of the spotted shark. The skin of the fish is first stripped, then extended on a table, and covered with bruised mustard-seed: it is thus exposed to the weather for several days, and afterwards tanned. The best shagreen imported from Constantinople, is of a brownish cast, and very hard; but, when immersed in water, it becomes soft and pliable; and may be dyed to any colour. It is often counterfeited, by preparing Morocco leather in the same manner as the skin of the fish. This fraud may be detected by the surface of the spurious manufacture peeling or scaling off, while that of the genuine article remains perfectly sound. Shagreen is employed principally in the manufacture of cases for mathematical instruments.

Chamois, is a kind of leather, either dressed in oil, or tanned, and much esteemed for its softness and pliancy. It is prepared from the skin of the *chamois*, a wild goat, on the mountains of Dauphiny, Savoy, Piedmont, and the Pyrenees. Besides the softness and warmth of the leather, it has the faculty of bearing soap without hurt. The true chamois leather is very frequently counterfeited with common goat, kid, and even sheep skin.

French mode of rendering Leather, Canvas, Linen, &c. Water-proof. The following substances are first well ground and mixed together, viz. 1½ lb. of the acetate of lead (sugar of lead,) and 1½ lb. of very finely powdered pumice stone; these are then boiled in 100 gallons of the best linseed oil, over a gentle fire, that the oil may not be burned. The liquid should be kept boiling, until it becomes of such a consistence, that after being mixed with a third part of its weight of pipe-clay, it should be of the thickness of molasses. It is then left to clear itself, and afterwards passed through a fine lawn sieve. About 10 pounds of pipe-clay is then to be ground with a solution of the best glue, and so mixed as to be of the consistence of lard; to this mixture is to be added the varnish by degrees, mixing and stirring it well at every addition, with a spatula of wood, until it has become perfectly fluid. The colour is then added, consisting of 1½ lb. of calcined umber, and 1½ lb. of white lead ground in oil. In order to apply it, the linen is stretched over a frame of wood, and the composition spread by means of a broad spatula, about 3 inches wide and 9 inches long. The frame is then inverted, and the composition applied on the other side of the cloth; it is allowed to remain for a week on the frame to dry, and then taken off for use. The cloth so prepared is used for riding cloaks, and as covers for carriages, &c. The same composition is applied to leather and skins, but to produce a glossy brilliant appearance, a varnish is employed, consisting of 5 lb. of the oil varnish, as before mentioned, and an equal weight of clear resin, heated together over a fire until the resin is dissolved; to these are added 2 lbs. of oil of turpentine, with which has been ground some colour, to give it the required tint, and cleared of all impurities by passing through a fine lawn sieve. This varnish is laid on with a brush, and when quite hard is rubbed over with pumice stone and water, and afterwards well washed. Two or three coats of this varnish are given to it, each coat being well dried before another is laid on, by which is produced a varnish of such brilliancy as to rival the best japan.

The following recipe, although it will not render boots and shoes entirely water-proof, will make them much more impervious to wet, more durable and pliable, and prevent their cracking:—Take one pint of boiled linseed oil, two ounces of bees-wax, two ounces of spirits of turpentine, and one ounce of Burgundy-pitch, melted carefully over a slow fire. With this composition, rub the soles and upper leathers, when new, with a small piece of sponge, in the sun, or at a distance from the fire; rub them as often as they become dry, until the leather is fully saturated.

Another Method. Mix equal parts of mutton-fat, bees-wax, and sweet-oil together, in a small gallipot, and heat them over the fire till melted; then, after the mixture has cooled a little, apply it to the shoes plentifully, particularly about the welt and seams, and that will render them entirely water-proof.

LEDGE, a long ridge of rocks near the surface of the sea.

LEDGES, small pieces of timber placed athwart ships, under the decks, in the intervals between the beams.

LEE, an epithet to distinguish that half of the horizon to which the wind is directed from the other part whence it arises, which latter is accordingly called, to windward. This expression is chiefly used when the wind crosses the line of a ship's course; so that all on one side of her is called, to windward; and all on the opposite side, to leeward; and hence,

Under the LEE, implies farther from that part of the horizon from whence the wind blows, as, *Under the lee of the land*, i. e. at a short distance from the shore which lies in the direction of the wind. This phrase indicates the situation of a vessel anchored or sailing near the weather shore, where there is always smoother water than at a great distance from it. To lay a ship by the lee, or to come up by the lee, is to bring her so that all her sails lie flat against her masts and shrouds, and that the wind may come right upon her broadside.

LEE Boards, strong frames of plank affixed to the sides of flat-bottomed vessels, such as river barges, &c. which draw but little water; these, by being let down into the water when the vessel is close-hauled, prevent her from falling leeward. **LEE Fanga**, are ropes reeved into the cingles of a yacht or hoy's sails. *The LEE Gage*, implies further from the point whence the wind blows than another vessel. *Take care of the LEE*

Hatch, is a word of command to the man at the helm, to take care that the ship do not go to the leeward of her course. **LEE Lurches**, the sudden and violent rolls which a ship often takes to leeward in a high sea, particularly when a large wave strikes her on the weather side.

A LEE Shore; a ship is said to be on a lee-shore, when she is near the land, with the wind blowing right upon it.

LEE Side, all that part of a ship or boat which lies between the mast and the side farthest from the direction of the wind; or that half of a ship which is pressed down towards the water by the effort of the sails, as separated from the other half by a line drawn through the middle of her length; that part of the ship which lies to the windward of this line is accordingly called the weather side. Thus, if a ship sail southward with the wind at east, then is her starboard or right side the lee-side; and the larboard or left, the weather-side.

LEE Tide, is a tide running in the same direction that the wind blows, and is directly contrary to a tide under the lee which implies a stream in an opposite direction to the wind.

To LEEWARD, denotes towards that part of the horizon which lies under the lee, or whither the wind blows.

LEEWARD Ship, is one that is not fast by the wind, or which does not sail so near the wind, nor make so good way, as she should; or which is much to leeward of her course, when sailing close-hauled.

LEE Way, or **Leeward Way**, is the lateral movement of a ship to the leeward of her course, or the angle which the line of her way makes with her keel when she is close-hauled. This movement is produced by the mutual effort of the wind and sea upon her side, forcing her to leeward of the line upon which she appears to sail; and in this situation her course is necessarily a compound of the two motions by which she is impelled. All ships are apt to make some lee-way; so that in casting up the log-book, something must be allowed for lee-way. But the lee-way made by different ships, under the same circumstances, will be different; and even the same ship, with different lading, and having more or less sail on board, will make more or less lee-way. The ordinary rules of allowing for it, as given by Mr. John Buckler to Mr. William Jones, who first published them about the year 1702, are these:—1. When a ship is close-hauled, has all her sails set, the water smooth, and a moderate gale of wind, she is then supposed to make little or no lee-way. 2. Allow one point when it blows so fresh that the small sails are taken in. 3. Allow two points, when the topsail must be close reefed. 4. Allow two points and a half when one topsail must be handed. 5. Allow three points and a half when both topsails are to be taken in. 6. Allow four points when the fore-course is handed. 7. Allow five points when trying under the main sail only. 8. Allow six points when both main and fore courses are taken in. 9. Allow seven points when the ship tries a-hull, or all sails are handed. When the wind has blown hard in either quarter, and shifts across the meridian into the next quarter, the lee-way will be lessened. But in all these cases respect must be had to the roughness of the sea with the trim of the ship; and hence the mariner will be able to correct his course.

LEECHES, *Water Snails*. To apply leeches effectually, the skin should be soft, and if lotions have been used, the skin must be cleanly washed, and the leeches will bite very readily when they are fresh and hungry. The best mode of applying them is to let the leech crawl on a dry piece of linen for a little time; or better, if it have been kept in a vessel without water for some time beforehand, then to take it in a bit of soft linen between the thumb and finger, and when it projects its pointed mouth between the folds of the linen, to direct it to the spot intended for it to act on. In this way the leech will generally fasten at the first touch, and it will at all events fasten more readily, since it is prevented from covering the skin with slime, and thus sheathing it from its own bite and that of other leeches. The most skilful appliers of leeches use this method, and they gain celebrity by thus throwing them on the part, as some of them express it.

Another way is, to put the leeches into a wine glass or pill-box, and then to invert the glass or box on the proper part. This method does not answer when the leeches are not lively, for they will fix on the sides of the vessel, so as not to be again

made to touch the skin. This difficulty may generally be obviated by putting more leeches into the vessel or vessels than are wished to be applied, and removing them when the proper number have adhered.

In cases of difficulty, it is often advantageous to cover the part with cream or milk; or better, to touch the head of the leech with a drop of vinegar; or to make small incisions in the skin (of the operator perhaps, if the patient be a sleeping child) by means of a lancet: or, if one leech have adhered, to take it off again, and use the blood to entice others to do likewise. Mr. Thomson says, in the London Dispensatory, that a leech may certainly be made to bite on any assigned spot, by putting it into a quill which is open at both ends, and after placing the end containing the leech's head on the part, stopping up the other end by means of the finger. This information is valuable, at least if the plan prove generally successful, in cases where leeches are required close to an important part, as near the eye or on the gums, &c.; but it is to be feared that the quill would be as likely to fail as the common leech-glass, both being used on the same principle; and the latter being confessedly an ineffective instrument.

The pain of biting generally ceases in a short time after the leech has adhered; but if the patient be so placed as that the leech hangs as it were from the point of adhesion, the pain is in some individuals increased, and continues till the leech falls off. Leeches should not remain on the part for more than ten or fifteen minutes; if they do not then fall off, it will be found that they have been sluggish, and are not full, and the same thing will be shewn by the want of that vermicular motion on the neck of the leech, which is so perceptible when it draws vigorously. In these cases it may often be made more active by touching its head with vinegar.

As it sometimes happens that leeches, when indolent, will thus remain on the part for hours, it is better to remove them when they are disposed to suck. This may be done by the application of a very little salt to their heads, and as the after-bleeding is generally more advantageous than the drawing of the leech itself, very little loss is sustained by removing them before they are filled with blood.*

The Treatment of Leeches after their Removal from the Skin.—Great waste is occasioned by the unskillfulness in attending to leeches after they fall off. By proper care they may be made to act again and again; for, when it is considered that blood is the natural food of the leech, it must follow, that some fault in our treatment causes their death, and not their having made a hearty meal on food that is natural to them. It may happen, indeed, that the blood in certain states of disease acts as a poison, and destroys them; many persons having stated that they fall off dead, in some cases, before any application is made to them; but this is at least problematical, and perhaps unlikely. The common practice of covering them with salt is almost always destructive; and, even by sprinkling a small quantity on their bodies, if death do not follow, it generally happens that the leech is blistered by the salt, and made incapable of acting again for a considerable time. Squeezing out the blood is better than the application of salt in any form; but the best mode is to touch them with vinegar, which, if sparingly applied, will make them vomit, so that they may be re-applied again immediately, even to the third or fourth time, or, by returning them into clean water, be ready for another occasion. When leeches are treated in this way, and especially if they be allowed to keep, perhaps, a fourth part of the blood which they have swallowed, they are not only capable of acting repeatedly, but, in skilful hands, may be made to grow to an immense size.

Under one gentleman's care, a set of leeches were in this way preserved for a great length of time, and at last they grew to the length of nearly eight inches. It was want of care that destroyed them, even after all this. These leeches were not once emptied of their blood, and yet they were often used again at an interval of only a few days. We understand it is the practice of some surgeons, when leeches have been scarce, and it has been considered requisite to take a large quantity of

blood from a patient, to cut off the tail of the leech, when it has nearly filled itself; the creature keeps on sucking to fill itself, and appears to be unconscious of its being employed merely as a funnel or a spout.

LEECHES, the borders or edges of a sail, which are either sloping or perpendicular; those of the square-sails, i.e. the sails whose tops and bottoms are parallel to the deck, or at right angles with the mast, are denominated from the ship's side, as the starboard-leech of the main-sail, the lee-leech of the fore-top-sail; but the sails which are fixed obliquely on the masts have their leeches named from their situation with regard to the ship's length, as the fore-leech of the mizzen, the after-leech of the jib, &c.

LEECH Lines, ropes fastened to the middle of the leeches of the mainsail and foresail, and communicating with blocks under the opposite sides of the top, whence they pass downwards to the deck, serving to truss those sails up to the yards. **Harbour LEECH Lines**, ropes made fast at the middle of the topsail yards, then passing round the leeches of the topsails, and through blocks upon the topsail-tye, serving to truss the sails very close up to the yard, previous to their being furled in a body. **LEECH Rope**, a name given to that part of the bolt-rope to which the border or edge of a sail is sewed. In all sails whose opposite leeches are of the same length, it is terminated above by the earing, and below by the clue.

LEET, a little court held within a manor.

LEGION, in Roman antiquity, a body of foot, which consisted of ten cohorts or battalions, each cohort consisting of six centuries, commanded by a centurion, and when full, a century was 100 men, but the numbers were often incomplete, particularly during a campaign.

LEGISLATOR, a lawgiver, or a person who establishes the policy and laws of a state. Such was Moses, among the Jews; Lycurgus, among the Lacedæmonians, &c.

LEMMA, in Mathematics, denotes a previous proposition, laid down in order to clear the way for some following demonstration, and prefixed either to theorems, in order to render their demonstration less perplexed and intricate, or to problems, to make their solution more easy and short. Thus, to prove a pyramid one-third of a prism or parallelopiped of the same base and height with it, the demonstration of which in the ordinary way is difficult and troublesome, this lemma may be premised, which is proved in the rules of progression, viz. that the sum of a series of square numbers in arithmetical progression, beginning from 0, as 1, 4, 9, 16, 25, 36, &c. is always subtriple of the sum of as many terms, each equal to the greatest; or, is always one-third of the greatest term multiplied by the number of terms.

LEMONS. SALT OF, used to remove ink-stains from linen, is the native salt of sorrel, the super-oxalate of potash. The effect is produced by the oxalic acid dissolving with facility the oxide of iron in the ink, on the combination of which with the tannin and gallic acid, the colour depends; while, at the same time, it can be used without any risk of injury to the cloth, on which it has no effect.

LEMURES, in Antiquity, spirits or hobgoblins; restless ghosts of departed persons, who return to terrify and torment the living. These are the same with larvæ, which the ancients imagined to wander round the world, to frighten good people and plague the bad. For which reason, they had at Rome lumeria, or feasts, instituted to appease the manes of the defunct. See **LARES**.

LENGTHENING, the operation of cutting a ship down across the middle, and adding a certain portion to her length. This is performed by sawing her planks asunder in different parts of her length, on each side of the midship frame, to prevent her from being weakened too much in one place. The two ends are then drawn apart to a limited distance, which must be equal to the proposed addition of length. An intermediate piece of timber is next added to the keel, upon which a sufficient number of timbers are erected to fill up the vacancy produced by the separation. The two parts of the keelson are afterwards united by an additional piece, which is scored down upon the floor timbers; and as many beams as may be necessary are fixed across the ship in the interval. Finally, the planks of the side are prolonged so as to unite with each other,

* According to one gentleman's experiments, the largest leech is not more than a drachm heavier when full, than before application. If so, small ones cannot draw away more than half a tea-spoonful of blood.

and those of the ceiling refitted in the same manner, by which the whole process is completed.

LENS, a piece of glass or other transparent substance, having its two surfaces so formed that the rays of light in passing through it have their direction changed, and made to converge or diverge from their original parallelism, or to become parallel after converging or diverging. Lenses receive particular denominations according to their form; as *convex*, *concave*, *plane convex*, *plane concave*, *lenses*, and *meniscuses*.

Convex LENS, is one which is thickest in the middle. If only one side is convex and the other plane, it is called a *plane convex lens*, such is A P, in the following figure; but if it be convex on both sides, it is called a *convex convex*, or *double convex lens*, as B G.

Concave LENS, is that which is thinnest in the middle; but it is also divided into *plane concave* and *convex concave*, as in the former case; such are two lenses C H, D I.

And when the lens is concave on one side and convex on the other, it is called a *meniscus*, as E K, in the above figure. In every lens the right line perpendicular to the two surfaces is called the *axis* of the lens; the points where the axis cuts the surface, are called the *vertices* of the lens; also the middle point between them is called the *centre*, and the distance between them the *diameter*. Some confine the term lenses to such as do not exceed half an inch diameter, those that exceed this being termed *lenticular glasses*.

Lenses are either blown or ground. **Blown Lenses**, are small globules of glass melted in the flame of a lamp by a blow-pipe, or otherwise. **Ground Lenses**, are such as are ground to the required form by means of machinery for this purpose.

The **Lens Grinding Machine** is of varied form and construction. This figure represents one of these machines, so contrived as to turn a sphere at one and the same time on two axes, cutting each other at right angles, and producing the segment of a true sphere merely by turning round the wheels without any care or skill of the workman. A is a globe covered with cement, on which are fixed the pieces of glass to be ground; this globe is fastened to the axis, and turns with the wheel B. C is the brass cup that polishes the glass. This is fastened to the axis, and turns with the wheel D. The motion of the cup C, therefore, is at right angles to the motion of the globe A; whence it follows demonstrably, that the pieces of glass ground by this double motion must be formed into the segments of spheres.

LENT, a solemn time of fasting in the Christian church, observed as a time of humiliation before Easter, the great festival of our Saviour's resurrection.

LEO MINOR, the *Little Lion*, it has been said, owes its place in the heavens to the fable of Hercules killing the Nemean lion. This is erroneous, for Leo Minor was composed out of the *stellæ informes* of the ancients. In the Egyptian calendar we find the sign Leo to contain the figures of two lions, and the head of a third. The *Little Lion* is a paratantillon to Leo of the zodiac.

Boundaries and Contents.—North by Ursa Major, east by Coma Berenices, south by Leo, and west by Lynx. This constellation contains 53 stars, viz. one of the 3d magnitude, six of the fourth, eleven of the 5th, &c. and the upper part of the animal's head does not set in London. The position of Leo Minor is easily ascertained, for it is composed as it were of three knots of stars, one at the head and fore feet, a second on the body, and a third at the tail; and the central group, deter-

60.

mined by a line drawn from Regulus, to the Pointers, enables us to fix on the two others to the east and west.

Leo, the Lion, is the fifth sign in the order of the zodiac, and the second of the summer signs. According to the fixed zodiac and the astronomical year, the Sun enters Leo on the 23d of July; but reckoning agreeably to the precession of the equinoxes and the moveable zodiac of the sidereal year, the Sun enters this sign on the 8th of August. The Earth is at this period in Aquarius, and the Sun, as seen from the Earth, appears in Leo. For, in whatever part of the ecliptic we apprehend the Sun to be, the Earth is 180° removed from that point. As the Earth goes round the Sun, the North Pole keeps constantly towards one part of the heavens; it now approaches nearer its orbit than in the preceding sign, and the days and nights are consequently coming nearer to an equality.

Boundaries and Contents of Leo.—This sign is bounded on the north by Leo Minor, east by Virgo, south by Sextans, and west by Cancer; it contains 25 stars, viz. two of the 1st magnitude, two of the 2d, six of the 3d, thirteen of the 4th, &c. The chief star is Regulus, situated on the Ecliptic, and sometimes called *Cor Leonis*, "the Lion's heart." In the tail of the Lion we find Denebola, also a star of the first magnitude. The declination of Regulus is 12° 56' 26" north, and its right ascension 149° 25' 29". Regulus rises in the E. N. E. part of the horizon, as does also Denebola, but about 4° more to the N. and 1 hour 30 minutes after Regulus. Regulus rises and culminates, to the inhabitants of London, for the first of every month, agreeably to the following Table: Merid. Alt. 51° 25' 26".

MONTH.	Rises.	CULM.	MONTH.	Rises.	CULM.
	ho. mi.	ho. mi.		ho. mi.	ho. mi.
Jan.	10 15 A.	3 10 M.	July	3 12 M.	3 10 A.
Feb.	6 0 A.	1 0 M.	Aug.	6 0 M.	1 14 A.
Mar.	4 10 A.	10 9 A.	Sept.	4 0 M.	11 15 M.
April	2 15 A.	9 16 A.	Oct.	2 15 M.	9 27 M.
May	12 20 A.	7 25 A.	Nov.	12 22 M.	7 30 M.
June	10 8 M.	5 23 A.	Dec.	10 22 M.	5 27 M.

The sign *Leo* is chiefly situated north of the Ecliptic, passing over the northern parts of the torrid zone. And in the heavens the position of Regulus and Denebola may be thus found.

LEPAS, the *Acorn*, a genus of shell-fish, belonging to the order of *vermes testacea*.

LEPIDIUM, *DIPTANDER*, or *PEPPERWORT*, a genus of plants belonging to the *tetradynamia* class, and in the natural method ranking under the 30th order, *siliquosae*.

LEPIDOPTERA, in Zoology, an order of insects, with four wings, which are covered with imbricated scales.

LEPROSY, a foul cutaneous disease, appearing in dry, white, thin, scurfy scabs, either on the whole body, or only some parts of it, and usually attended with a violent itching and other pains. The leprosy is of various kinds, but Jews were particularly subject to that called *Elephantiasis*. Hence the Jewish law excluded lepers from communion with mankind, banishing them into the country or uninhabited places, without excepting even kings. When a leper was cleansed, he came to the city gate, and was there examined by the priests; after this he took two live birds to the temple, and fastened one of them to a wisp of cedar and hissop, tied together with a scarlet ribbon; the second bird was killed by the leper, and the blood of it received into a vessel of water; with this water the priest sprinkled the leper, dipping the wisp and the live bird into it: this done, the live bird was let go; and the leper having undergone this ceremony, was again admitted into society, and to the use of things sacred. See Levit. xiii. 46, 47, and xiv. 1, 2, &c.

L'ERMITE (*OISEAU*), a constellation formed some years ago by M. Monnier, under the northern scale of the Celestial Balance. Dr. Jamieson, on his Celestial Atlas, has transformed *L'Ermite Oiseau* into the sage-looking *Nectus*, a bird, which, considering the frequency it is met with on all Egyptian monuments, it appears strange our astronomers have not long ere this transferred among the celestials.

LETHARGY, (a word of Greek derivation,) in Medicine, is a disease consisting of a profound drowsiness or sleepiness, from which the patient can scarcely be awaked; or, if awaked,

7 F

The level *qr* is surmounted by a telescope O M I, and the whole fixed on a stand resembling that of the improved theodolite, the adjustment of the instrument being effected by means of the screws shewn in the figure. The telescope is a chromatic, about 18 inches long, for viewing remote objects. O I are the Y supporters in which it rests. The spirit level shews when the instrument is properly adjusted. The supporters are fixed in the plate K I K. The screws C, Q, G, H, H, E, and F, are severally used for adjusting the instrument, which is supported by three legs A, B, D. The usual height of the instrument is about 6½ feet; but as an hour's practice will give more information than pages of description, and as the telescope answers the same purpose, we shall refer the reader to that article.

LEVELLING, the finding a line parallel to the horizon at one or more stations, to determine the height or depth of one place with respect to another, for laying out grounds even, regulating descents, draining morasses, conducting water, &c.

Two or more places are on a true level when they are equally distant from the centre of the earth. Also one place is higher than another, or out of level with it, when it is farther from the centre of the earth; and a line equally distant from that centre in all its points, is called the line of true level.

Hence, because the earth is round, that line must be a curve, and make a part of the earth's circumference, or at least be parallel to it, or concentric with it; as the line B C F G, which has all its points equally distant from A, the centre of the earth, considering it as a perfect globe.

But the line of sight B D E, &c. given by the operations of levels,

is a tangent, or a right line perpendicular to the semi-diameter of the earth at the point of contact B, rising always higher above the true line of level, the farther the distance is, is called the apparent line of level. Thus, C D is the height of the apparent level, above the true level, at the distance B C or B D; also E F is the excess of height at F, and G H at G, &c. The difference, it is evident, is always equal to the excess of the secant of the arch of distance above the radius of the earth.

The common methods of levelling are sufficient for laying pavements of walks, or for conveying water to small distances, &c.; but in more extensive operations, as in levelling the bottoms of canals, which are to convey water to the distance of many miles, and such like, the difference between the true and the apparent level must be taken into the account.

Now the difference C D between the true and apparent level at any distance B C or B D, may be found thus: by a well-known property of the circle ($2 A C + C D$); $B D :: B D : C D$; or because the diameter of the earth is so great with respect to the line C D, at all distances to which an operation of levelling commonly extends, that $2 A C$ may be safely taken for $2 A C + C D$ in that proportion without any sensible error, it will be

$2 A C : B D :: B D : C D$, which therefore is $= \frac{B D^2}{2 A C}$, or $\frac{B C^2}{2 A C}$

nearly; that is, the difference between the true and apparent level is equal to the square of the distance between the places, divided by the diameter of the earth; and consequently it is always proportional to the square of the distance.

Now the diameter of the earth being nearly 7928 miles, if we first take $B C = 1$ mile, then the excess $\frac{B C^2}{2 A C}$ becomes $\frac{1}{7928}$ of

a mile, which is 7.962 inches, or almost eight inches, for the height of the apparent above the true level at the distance of one mile. Hence, proportioning the excesses in altitude according to the squares of the distances, the following table is obtained, shewing the height of the apparent above the true level for every 100 yards of distance on the one hand, and for every mile on the other.

By the following table of reductions, we can now level to almost any distance at one operation, whereas the ancients, being unacquainted with the correction answering to any distance, could only level from one twenty yards to another, when they had occasion to continue the work to a considerable extent.

Distance, or B. C.	Differ. of Level, or C. D.	Distance, or B. C.	Differ. of Level, or C. D.
Yards.	Inches.	Miles.	Feet. Inches.
100	0.026	$\frac{1}{4}$	0 0½
200	0.103	$\frac{1}{2}$	0 2
300	0.231	$\frac{3}{4}$	0 4½
400	0.411	1	0 8
500	0.643	2	2 8
600	0.925	3	6 0
700	1.260	4	10 7
800	1.643	5	16 7
900	2.081	6	23 11
1000	2.570	7	32 6
1100	3.110	8	42 6
1200	3.701	9	53 9
1300	4.344	10	66 4
1400	5.038	11	80 3
1500	5.784	12	95 7
1600	6.580	13	112 2
1700	7.425	14	130 1

This table answers several useful purposes. Thus, 1st, to find the height of the apparent level above the true, at any distance. If the given distance is in the table, the correction of level is found on the same line with it: thus at the distance of 1000 yards, the correction is 2.57, or two inches and a half nearly; and at the distance of 10 miles it is 66 feet 4 inches. But if the exact distance is not found in the table, then multiply the square of the distance in yards by 2.57, and then divide by 1,000,000, or cut off six places on the right for decimals, the rest are inches: or multiply the square of the distance in miles by 66 feet 4 inches, and divide by 100.

2dly. To find the extent of the visible horizon, or how far an observer can see from any given height, on a horizontal plane, as at sea, &c. Suppose the eye of the observer, on the top of a ship's mast at sea, is the height of 130 feet above the water, he will then see about 14 miles all around. Or from the top of a cliff by the sea-side, the height of which is 66 feet, a person may see to the distance of near 10 miles on the surface of the sea. Also when the top of a hill, or the light in a light-house, or such like, whose height is 130 feet, first comes into the view of an eye on board a ship, the table shews that the distance of the ship from it is 14 miles, if the eye is at the surface of the water; but if the height of the eye in the ship is 80 feet, then the distance will be increased by near 11 miles, making in all about 25 miles in distance.

3dly. Suppose a spring on one side of a hill, and a house on an opposite hill, with a valley between them, that the spring seen from the house appears by a levelling instrument on a level with the foundation of the house, which suppose is at a mile distance from it; then is the spring eight inches above the true level of a house; and this difference would be barely sufficient for the water to be brought in pipes from the spring to the house, the pipes being laid all the way in the ground.

4thly. If the height or distance exceed the limits of the table, then, first, if the distance be given, divide it by 2, or by 3, or by 4, &c. till the quotient come within the distances in the table; then take out the height answering to the quotient, and multiply it by the square of the divisor, that is, by 4, or 9, or 16, &c. for the height required. Thus, if the top of a hill is just seen at the distance of 10 miles, then 40 divided by 4 gives 10, to which in the table answer 66½ feet, which being multiplied by 16, the square of 4, gives 1061½ feet for the height of the hill. But when the height is given, divide it by one of these square numbers, 4, 9, 16, 25, &c. till the quotient come within the limits of the table, and multiply the quotient by the square root of the divisor; that is, by 2, or 3, or 4, or 5, &c. for the distance sought; so when the top of the peak of Teneriffe, said to be about 3 miles, or 15,840 feet high, just comes into view at sea, divide 15,840 by 225, or the square of 15, and the quotient is 70 nearly; to which in the table answers by proportion nearly 104 miles; then multiplying 104 by 15, gives 1560 miles and ½ the distance of the hill.

lege of physicians, or by the bishop of the diocese. A person practising physic without such license, in case his patient dies under his hands, is guilty of felony in the eye of the law.

LICHEN, in Botany, a name borrowed by the Romans from the Greeks for the disease called a tetter or ringworm, and applied by both to a plant of a mossy nature, growing on stones, which was thought to be a cure for such complaints.

LIE, in Morals, denotes a criminal breach of veracity. Archdeacon Paley, in treating of this subject, observes, that there are falsehoods which are not lies; that is, which are not criminal: and there are lies, which are not literally and directly false.

LIEGE, **LEIGIS**, in Law, properly signifies a vassal, who holds a kind of fee, that binds him in a closer obligation to his lord than other people.

LIENTERY, a flux of the belly, in which the aliments are discharged as they are swallowed, or very little altered in colour or substance.

LIEUTENANT, an officer who supplies the place, and discharges the office, of a superior in his absence. Of these, some are civil, as the lords-lieutenants of kingdoms, and the lords-lieutenants of counties; and others are military, as the lieutenant-general, lieutenant-general of the artillery, lieutenant-colonel, lieutenant of artillery of the Tower, lieutenants of horse, foot, ships of war, &c.

LIFE, a term that implies the existence and duration of soul and body, or the period of their union.

LIFE ANNUITIES, are such periodical payments as depend on the continuance of some particular life or lives; and they may be distinguished into lives, to commence immediately; and annuities, to commence at some future period, called reversionary annuities.

The value or present worth of an annuity for any proposed life or lives, it is evident depends on two circumstances; the interest of money, and the chance or expectation of the continuance of life. Upon the former only depends the value or present worth of an annuity certain, or that which is not subject to the continuance of a life or other contingency; but the expectation of life being a thing not certain, but only possessing a certain chance, it is evident, that the value of the certain annuity, as stated above, must be diminished in proportion as the expectancy is below certainty; thus, if the present value of an annuity certain be any sum, as suppose £100, and the value and expectancy of the life be one-half, then the value of the life annuity will be only half of the former, or £50; and if the value of the life be only one-third, the value of the life annuity will be but one-third of £100, that is, £33. 6s. 8d. and so on.

The measure of the value or expectancy of life, depends on the proportion of the number of persons that die, out of a given number, in the time proposed; thus, if fifty persons die out of one hundred, in any proposed time, then half the number only remaining alive, any one person has an equal chance to live or die in that time, or the value of his life for that time is one-half; but if two-thirds of the number die in the time proposed, or only one-third remain alive, then the value of any life is one-third; and if three-quarters of the number die, or only one-quarter remain alive, then the value of any life is but one-quarter; and so on. In these proportions then must the value of the annuity certain be diminished, to give the value of the life annuity. It is plain, therefore, that in this business it is necessary to know the value of life at all the different ages, from some table of observations on the mortality of mankind, which may shew the proportion of the persons living, out of a given number, at the end of any proposed time; or from some certain hypothesis, or assumed principle. It may not, therefore, be improper to insert here a comparative view of two of the principal tables that have been given of this kind, as the following, where the first column shews the age, and the other columns the number of persons living at that age, out of 1000 born, or of the age 0, in the first line of each column.

The uses of these tables may be exemplified in the following problems:—

Problem 1.—To find the Probability or Proportion of Chance, that a Person at a given Age continues in being a proposed number of Years.—Thus, suppose the age to be 40, and the number of

years proposed 15; then to calculate by the table of the probabilities for London, in table 1, against 40 years stands 214; and against 55 years, the age to which the person must arrive, stands 120; which shews, that of 214 persons who attain to the age of 40, only 120 of them reach the age of 55, and consequently 94 die between the ages of 40 and 55. It is evident, therefore, that the odds for attaining the proposed age of 55, are as 120 to 94, or as 9 to 7 nearly.

Problem 2.—To find the Value of an Annuity for a proposed Life.—This problem is resolved from table 2, by looking against the given age, and under the proposed rate of interest; then the corresponding quantity shews the number of years' purchase required. For example, if the given age be 36, the rate of interest 4 per cent. and the proposed annuity £250. Then in the table it appears, that the value is 12.1 years purchase, or 12.1 times £250, that is, £3025.1. After the same manner, the answer will be found in any other case falling within the limits of the table. But as there may sometimes be occasion to know the values of lives computed at higher rates of interest than those in the table, the two following practical rules are subjoined, by which the problem is resolved independent of tables.

Rule 1. When the given age is not less than 45 years, nor greater than 85, subtract it from 92; then multiply the remainder by the perpetuity, and divide the product by the said remainder added to 2½ times the perpetuity; so shall the quotient be the number of years' purchase required. Where note, that by the perpetuity is meant the number of years' purchase of the fee-simple; found by dividing 100 by the rate per cent. at which interest is reckoned.

Example. Let the given age be 50 years, and the rate of interest 10 per cent. Then subtracting 50 from 92, there remains 42; which multiplied by 10 the perpetuity, gives 420; and this divided by 67, the remainder increased by 2½ times 10 the perpetuity, gives 6.3 nearly, for the number of years' purchase. Therefore, supposing the annuity to be £100, its value in present money will be £630.

Rule 2. When the age is between 10 and 45 years, take eight-tenths of what it wants of 45, which divide by the rate per cent. increased by 1.2; then if the quotient be added to the value of a life of 45 years, found by the preceding rule, there will be obtained the number of years' purchase in this case. For example, let the proposed age be 20 years, and the rate of interest 5 per cent. Here taking 20 from 45, there remains 25; eight-tenths of which is 20; which divided by 6.2, quotes 3.2; and this added to 9.8, the value of a life of 45, found by the former rule, gives 13 for the number of years' purchase that a life of 20 ought to be valued at. And the conclusions derived by these rules are said, by Simpson, to be so near the true values, computed from real observations, as seldom to differ from them by more than one-tenth or two-tenths of one year's purchase.

The observations here alluded to, are those which are founded on the London bills of mortality. And a similar method of solution, accommodated to the Breslaw observations, will be as follows: viz. Multiply the difference between the given age and 85 years by the perpetuity, and divide the product by eight-tenths of the said difference, increased by double the perpetuity for the answer; which, from 8 to 80 years of age, will commonly come within less than one-eighth of a year's purchase of the truth.

Problem 3.—To find the Value of an Annuity for the longest of two Lives; that is, for as long as either of them continue in being.—In table 3, find the age of the youngest life, or the nearest to it, in col. 1, and the age of the elder in col. 2; then against this last is the answer in the proper column of interest.

Example. So if the two ages be 15 and 40, then the value of the annuity upon the longest of two such lives,

is 21.1 years' purchase,	at 3 per cent.
or 17.9	at 4
or 15.7	at 5

Note. In the last two problems, if the younger age, or the rate of interest, be not exactly found in the tables, the nearest to them may be taken; and then, by proportion, the value for the true numbers will be nearly found.

TABLE I. Exhibiting the Decrease of Life, at all Ages, from 1 Year to 90, as deduced from the Bills of Mortality in London and Northampton.

Ages.	London.	Northampton.	Ages.	London.	Northampton.	Ages.	London.	Northampton.	Ages.	London.	Northampton.
0	1000	1000	23	310	426	46	174	275	69	56	113

when placed upon water, although not so superficially or in such position without great care and exertion, as to preserve an adequate entrance for air into the organs of respiration.

The fact, however, is, that we are calculated to float conveniently for a considerable length of time, if we are possessed of sufficient self-confidence, and some art in balancing the body. Not always long enough, it must be admitted, for complete protection against the disasters which happen on the ocean, or even on rivers and canals; on all of which such multitudes are now scattered, by the industrious and adventurous spirit of the age. Nor, in cases of shipwreck, does the casual additional support of a mast, an oar, or a plank, always suffice to lend that buoyancy, on account of their unsteadiness, which the perils of the deep often demand. More fixed appendages, of various descriptions, have lately been introduced to the notice of the public, under the appellation of life-preservers; and boats upon a similar principle, under the name of life-boats, have been constructed, so as to be secured against sinking, even when filled with water and in the most tempestuous weather, for the purpose of rescuing from destruction those "who are ready to perish."

It has happened unfortunately with respect to most of the life-preservers, as they have been termed, that some difficulty has attached to their conveyance, application, or effect, which has either rendered them useless, or much less effectual than from their principle might have been expected; and accordingly in succession they have been disregarded. The importance of the object would not allow the attempt to be abandoned, and ingenious men still continue to exercise their inventive powers, in obviating the defects of their predecessors. The buoyancy of cork, which was formerly much resorted to, has given way to the superior buoyancy of air, and jackets distended with this very light fluid, or attached vessels of other forms filled with it, have been occasionally adopted. The effort has at length been successful; and air has become, by the invention of Scheffer, in another than the acknowledged sense of the term, a perfect life-preserver.

The simplicity and convenience of Scheffer's Life-preserver must be at once perceived. It consists of a hollow cylinder, formed without a seam, and perfectly air-tight, bent when distended with air and ready for use, as in fig. 2; or it is what may be termed a cylindrical ring, also without a seam, and also without the break which appears in the former, represented in fig. 1. Of this ring, the external diameter is generally about 22½ inches, the internal diameter about 12, and the diameter of the part containing the air about 5½, the dimensions varying of course, by being specially adapted to the size of the person by whom it is designed to be employed. By its form, it is well fitted for the place which it occupies, being situated beneath the arms; it does not press painfully upon the chest, and the suspension or support being placed so high, enables the lower part of the body and extremities, to act as a pendulum, in keeping the wearer vertical, or restoring him to that position, if thrown aside by the force of the waves. The two holes, one in each ring, the only openings, receive a small stop-cock, to which an ivory pipe is fixed. Through this pipe the air is injected by the mouth, and retained by the stop-cock; the adjustment and inflation only occupying the short space of one minute: when unexpanded, it folds up into a very small compass, so as to be conveyed in the pocket; and is also very portable, its weight, as I ascertained by weighing one of them, being but twelve ounces.

The public at Brighton last summer, had several opportunities of seeing Scheffer supported in the sea by his very valuable

Fig. 3.

able contrivance. He was taken in a boat about a mile from the shore, and there threw himself into the water. He became immediately buoyant, amused himself with swimming, or allowing himself to be tossed about by the waves, for more than an hour. He had along with him a spare preserver, by which he managed to shew, that in the manner represented in the vignette, he could have placed it upon a person in danger of sinking, and even have used several for different persons in similar danger, who would all be rendered safe, until they could have been collected and preserved by a life-boat. His experiment succeeded to the satisfaction of a large number of spectators. The situation from which the exhibition was viewed, the head of the chain pier, was particularly favourable for watching the motions of the adventurer: and the sea being very rough, gave occasion to observe how effectually the buoyant girdle controlled that power, by which an unprotected man must have been speedily engulfed.

LIFTS, certain ropes descending from the cap and mast head. Their use is to keep the yard in equilibrio, or to pull one of its extremities higher than the other, if occasion requires; but particularly to support the weight of it when a number of seamen are employed thereon to furl or reef the sail. In some merchant vessels the lifts of the topsail yards, called the top-sail lifts, are also used as sheets to extend the clues of the top-gallant sail. The yards are said to be squared by the lifts, when they hang at right angles with the mast, i. e. parallel with the horizon when the vessel is upright in the water.

LIGAMENT, in Anatomy, a strong compact substance, serving to join two bones together. A ligament is more flexible than a cartilage, not easily ruptured or torn, and does not yield, or at least very little, when pulled.

LIGATURE, in Surgery, is a cord, band, or string; or the binding any part of the body with a cord, band, fillet, &c. whether of leather, linen, or any other matter. Ligatures are used to extend or replace bones that are broken or dislocated; to tie the patients down in lithotomy and amputations; to tie upon the veins in phlebotomy, on the arteries in amputations, or in large wounds; to secure the splints that are applied to fractures; to tie up the processes of the peritonæum with the spermatic vessels in castration; and lastly, in taking off warts or other excrescences by ligature. Ligature is also used to signify a kind of bandage or fillet, tied round the neck, arm, leg, or other part of the bodies of men or beasts, to divert or drive off some disease, accident, &c.

LIGATURES, among printers, are types consisting of two letters or characters joined together; as ff, fl, n. The old editions of Greek authors are extremely full of ligatures; the ligatures of Stephens are by much the most beautiful. Some editions have been lately printed without any ligatures at all; and there was a design to explode them quite out of printing. Had this succeeded, the finest ancient editions would, in time, have grown useless; and the reading of old manuscripts would have been rendered almost impracticable to the learned themselves.

LIGHT, is that principle or substance which renders objects perceptible to our sense of seeing. This is, perhaps, one of the most interesting subjects that falls under the contemplation of the philosopher; at the same time it must be acknowledged to be one that is as little understood, and upon which opinions are as much divided, as any of the most abstruse subjects of philosophical inquiry. Some consider light as a fluid *per se*; while others consider it merely as a principle, and attribute it to a sort of pression, or vibration propagated from the luminous body through a subtile ethereal medium. But notwithstanding the imperfection of our knowledge, with regard to the nature and cause of light, repeated experiments and observations have made us acquainted with several of its properties; such as its INFLECTION, REFLECTION, REFRACTION, &c.; for which, see the respective articles.

Of the Motion of Light.—The ancients considered light as propagated from the sun and other luminous bodies instantaneously; but the observations of the moderns have shewn that this was an erroneous hypothesis, and that light, like any other projectile, employs a certain time in passing from one part of space to another, though the velocity of its motion is truly astonishing, as has been manifested in various ways; and,

first, from the eclipses of Jupiter's satellites. It was observed by Roemer, that the eclipses of those satellites happen sometimes sooner and sometimes later than the times given by the tables of them; and that the observation was before or after the computed times, according as the earth was near to, or farther from Jupiter, than the mean distance. Hence Roemer and Cassini both concluded that this circumstance depended on the distance of Jupiter from the earth: and that, to account for it, they must suppose that the light was about fourteen minutes in crossing the earth's orbit. This conclusion, however, was afterwards abandoned and attacked by Cassini himself. But Roemer's opinion found an able advocate in Dr. Halley; who removed Cassini's difficulty, and left Roemer's conclusion in its full force. Yet, in a memoir presented to the academy in 1709, M. Maraldi endeavoured to strengthen Cassini's arguments, when Roemer's doctrine found a new defender in Mr. Pound; see Phil. Trans. No. 136. It has since been found, by repeated observations, that when the earth is exactly between Jupiter and the sun, his satellites are seen eclipsed about eight minutes and a quarter sooner than they could be according to the tables; but when the earth is nearly in the opposite point of its orbit, these eclipses happen about eight minutes and a quarter later than the tables predict them. Hence then it is certain that the motion of light is not instantaneous, but that it takes up about sixteen minutes and a half of time to pass over a space equal to the diameter of the earth's orbit, which is near 180 millions of miles in length, or at the rate of near 200,000 miles per second; a conclusion which is placed beyond every possibility of doubt, by the aberration of the stars discovered by the celebrated Dr. Bradley.

Of the Momentum of Light.—We have before observed, that much diversity of opinion existed with regard to the materiality or immateriality of light, viz. whether it is a fluid *per se*, or whether it be merely a principle consisting in pulsations or vibrations; and thus rendered sensible to our optic nerve as sound is to our organs of hearing. The ingenious Dr. Franklin expresses his dissatisfaction with the doctrine, that light consists of particles of matter continually driven off from the sun's surface with so enormous a swiftness. "Must not," says he, "the smallest portion conceivable, have, with such a motion, a force exceeding that of a 24-pounder discharged from a cannon? Must not the sun diminish exceedingly by such a waste of matter; and the planets, instead of drawing nearer to him, as some have feared, recede to greater distances, through the lessened attraction? Yet these particles, with this amazing motion, will not drive before them, or remove, the least and slightest dust they meet with; and the sun appears to continue of his ancient dimensions, and his attendants move in their ancient orbits." He therefore conjectures that all the phenomena of light may be more properly solved, by supposing all space filled with a subtle elastic fluid, not visible when at rest, but which, by its vibrations, affects that fine sense in the eye, as those of the air affect the grosser organs of the ear; and even that different degrees of the vibration of this medium may cause the appearances of different colours. And the celebrated Euler has maintained the same hypothesis, urging some further objections to the materiality of light, beside those of Dr. Franklin, as above stated. These objections, however, Dr. Hoadley took considerable pains to obviate, though some of them still remain in full force. Others, on the contrary, have attempted to prove the materiality of light, by determining the momentum of its component particles, or by shewing that they have a force so as, by their impulse, to give motion to light bodies. M. Homberg, (1708,) imagined that he could not only disperse pieces of amethyst, and other light substances, by the impulse of the solar rays, but also that by throwing them upon the end of a kind of lever, connected with the spring of a watch, he could make it move sensibly quicker; from which, and other experiments, he inferred the weight of the particles of light. And Hartsoeker made pretensions of the same nature. But M. Du Fay and M. Mairan made other experiments of a more accurate kind, without the effects which the former had imagined, and which even proved that the effects mentioned by them were owing to currents of heated air produced by the burning glasses used in their experiments, or some other causes which they had overlooked. Mr. Michell endeavoured to ascertain the momentum

of light with still greater accuracy, and his endeavours were not altogether without success. Having found that the instrument he used acquired, from the impulse of the rays of light, a velocity of an inch in a second of time, he inferred that the quantity of matter contained in the rays falling upon the instrument in that time, amounted to no more than the 12 hundred millionth part of a grain. In the experiment, the light was collected from a surface of about three square feet; and as this surface reflected only about the half of what fell upon it, the quantity of matter contained in the solar rays, incident upon a square foot and a half of surface, in a second of time, ought to be no more than the 12 hundred millionth part of a grain, or upon one square foot only, the 18 hundred millionth part of a grain. But as the density of the rays of light at the surface of the sun, is 45,000 times greater than at the earth, there ought to issue from a square foot of the sun's surface, in one second of time, the 40 thousandth part of a grain of matter; that is, a little more than two grains a day, or about 4,752,000 grains, which is about 670 pounds avoirdupois in 6000 years, the time since the creation; a quantity which would have shortened the sun's semidiameter by no more than about 10 feet, if it be supposed of no greater density than water only. But, after all, these experiments and computations must be considered as very vague and unsatisfactory; and it may be added, that the material hypothesis is almost wholly rejected by the most celebrated chemists and philosophers of the present day.

LIGHT, is used in contradistinction to laden; a ship is therefore said to be light, when she has no cargo, or is not sufficiently ballasted.

LIGHTER, a large open flat-bottomed vessel, employed to carry goods to or from a ship.

Ballast Lighter, is a vessel fitted up to heave ballast from the bottom of a harbour or river, and to carry it to or from ships.

Covered or Close Lighter, is one furnished with a deck, in order to contain those merchandises which would be damaged by accidental wet, as also to prevent pillage.

LIGHT-HOUSE, a sort of tower erected upon a headland or point on the sea coast, or upon some rock in the sea, and having a great fire or light, formed by candles, &c. upon its top, in the night time, which is constantly attended by some careful person, so as to be seen at a great distance from the land. Its use is to direct the shipping on the coast, that might otherwise run ashore, or steer an improper course. The two most celebrated light-houses on the coast of Great Britain, are the *Eddystone* and *Bell-rock Light*: the former erected by the celebrated Smeaton. We have, under the word **PHAROS**, given the details of the erection and peculiar construction of the latter, which was executed by Robert Stevenson, Esq. from a model, and of the same dimensions, of the Eddystone, with the improvements on lighting which the recent progress in optics allowed the engineer to make.

Floating Light, differs from the preceding by its being erected on board a vessel which is strongly moored upon a sand or shallow, to warn ships from approaching too near it.

LIGHTNING. It is now universally allowed, that lightning is really an electrical explosion or phenomenon. Philosophers had not proceeded far in their experiments and inquiries on this subject, before they perceived the obvious analogy between lightning and electricity, and they produced many arguments to evince their similarity. But the method of proving this hypothesis was first proposed by Dr. Franklin, who, in the year 1749, conceived the practicability of drawing lightning from the clouds. See **METEOROLOGY** and **ELECTRICITY**.

LIGHTROOM, in a ship of war, a small apartment, having double glass windows towards the magazine. It is used to contain the lights by which the gunner and his assistants are enabled to fill their cartridges with powder, to be ready for action. Large ships of war generally have two lightrooms, viz. the after lightroom, attached to the after magazine; and the fore lightroom, which gives light to the fore or great magazine.

LIGNUM VITÆ. The lignum vitæ tree is a native of the West Indies, and the warmer parts of America: it rises to the height of forty feet, and measures from fifteen to eighteen inches in diameter; having a hard, brittle, brownish bark, not very thick. The wood is firm, ponderous, resinous, of a blackish yellow colour in the middle, and a hot aromatic taste.

LIGULATED, among botanists, an appellation given to such floscules as have a straight end turned downwards, with three indentures, but not separated into segments.

LIGUSTICUM, *Lorage*, a genus of plants belonging to the pentandria class; and in the natural method ranking under the 45th order, umbellatæ.

LIGUSTRUM, *Privet*, a genus of plants belonging to the diandria class; and in the natural method ranking under the 44th order, sepaliaræ.

LIMB, the outermost border, or graduated edge, of a quadrant, astrolabe, or such like mathematical instrument. The word is also used for the arch of the primitive circle, in any projection of the sphere in plano. Limb also signifies the outermost border or edge of the sun and moon; as, the upper limb or edge, the lower limb, the preceding limb or side; the following limb. Astronomers observe the upper or lower limb of the sun or moon, to find their true height, or that of the centre, which differs from the others by the semidiameter of the disc.

LIMBERS, or **LIMBER HOLES**, square holes cut through the lower part of a ship's floor timbers, very near the keel, forming a channel for water, and communicating with the pump well throughout the whole length of the floor. Every floor timber has two such holes cut through it, one on each side of the keelson.

LIMBER Boards, short pieces of plank, which form a part of the lining of a ship's floor close to the keelson, and immediately above the limbers. They are occasionally removed to clear the limbers of any filth by which they may be clogged, so as to interrupt the passage of the water to the pump well.

LIMBER Rope, a long rope frequently retained in the limber holes of a ship, in order to clear them, by pulling the rope backwards and forwards, so as to loosen any dirt by which they may be choked.

LIMB, one of those earthy substances, which exist in every part of the known world; it is found purest in limestone, marble, and chalk. None of these substances are lime, but are capable of becoming so by burning in a white heat. It may be also obtained perfectly pure by burning calcareous spars, and also by burning some pure white marbles. It may be procured also in a state of purity by dissolving oyster-shells in muriatic acid. It has been ascertained by Sir H. Davy to consist of oxygen and a metallic basis which he denominates calcium.

LIVESTONE. The native indurated carbonate of lime.

LIMIT, is a term used by mathematicians for some determinate quantity, to which a variable one continually approximates, and may come nearer to it than by any given difference, but can never go beyond it; in which sense a circle may be said to be the limit of all its inscribed and circumscribed polygons; because these, by increasing the number of their sides, can be made to be nearer equal to the circle than by any space that can be proposed, however small it may be.

LIMNING, the art of painting in water colours, in contradistinction to painting, which is done in oil colours. Limning is much the more ancient kind of painting. Till a Flemish painter, one John van Eyck, better known by the name of John of Bruges, found out the art of painting in oil, the painters all painted in water and in fresco, both on their walls, on wooden boards, and elsewhere. When they made use of boards, they usually glued a fine linen cloth over them, to prevent their opening; then laid on a ground of white; lastly, they mixed up their colours with water and size, or with water and yolks of eggs, well beaten with the branches of a fig tree, the juice whereof thus mixed with the eggs; and with this mixture they painted their pieces. In limning, all colours are proper enough, except the white made of lime, which is only used in fresco. The azure and ultramarine must always be mixed with size or gum; but there are always applied two layers of hot size before the size colours are laid on: the colours are all ground in water each by itself; and, as they are required in working, are diluted with size water. When the piece is finished, they go over it with the white of an egg well beaten; and then with varnish, if required.

To Limn, or Draw a Face in Colours. Having all the materials in readiness, lay the prepared colour on the card even and thin, free from hairs and spots, over the place where the

picture is to be. The ground being laid, and the party placed in a due position, begin the work, which is to be done in three sittings. At the first, you are only to dead-colour the face, which will require about two hours. At the second sitting, go over the work more curiously, adding its particular graces or deformities. At the third sitting, finish the whole, carefully remarking whatever may conduce to render the piece perfect, as the cast of the eyes, moles, scars, gestures, and the like.

LINE, in Geometry, is, according to Euclid's definition, that which has length without thickness. Lines are either right or curved: A *Right* or *Straight* **LINE**, is that which lies all in the same direction between its extremes or ends. A *Curve* **LINE**, is that which continually changes its direction. *Curve* **LINE**s, are again divided into *algebraical*, *geometrical*, and *mechanical*, or *transcendental*. An *Algebraical* or *Geometrical* **LINE**, is that which may be expressed, that is, the relation between its absciss and ordinate, by an algebraical equation. And such lines are divided into orders, according to the dimensions of the equations by which they are represented. *Mechanical* and *Transcendental* **LINE**s, are those which cannot be expressed by finite algebraical equations. Besides the above distinctions, lines receive other denominations according to their absolute or relative positions, as *parallel*, *perpendicular*, *oblique*, *tangential*, &c.; for which see the respective terms. **LINE**s have again other distinguishing appellations, as they are introduced into the different sciences of astronomy, geography, dialling, perspective, &c.; as, **LINE** of the *Apsides*; of the *Nodes*; *Horizontal*, *Hour*, *Equinoctial*, &c. **Lines**; each of which will be found illustrated under the respective articles.

LINE also denotes a French measure of length, being the 12th part of an arch.

LINE, a general name given to the arrangement or order in which a fleet of ships of war are disposed to engage an enemy. This disposition, which is the best calculated for the operations of naval war, is formed by drawing up the ships in a long file, or right line, prolonged from the keel of the hindmost to that of the foremost, and passing longitudinally through the keels of all the others from the van to the rear, so that they are, according to the sea phrase, in the wake of each other.

In the line or order of battle, all the ships in which it is composed are close-hauled upon the starboard or larboard tack, about fifty fathoms distant from each other. A fleet is more particularly drawn up in the line when in presence of an enemy. It ought to be formed in such a manner as that the ships should mutually sustain and reinforce each other, and yet preserve a sufficient space in their stations, to work or direct their movements with facility during the action. Thus they will be enabled effectually to cannonade the enemy, without incommoding the ships of their own squadron. In a line of battle, the weathermost fleet, or that which, in sea language, has the weather gage, is generally allowed to have the advantage, although there are several arguments on the other hand in favour of the leeward; accordingly, we shall endeavour to state the mutual advantages and disadvantages.

Advantages of the Weather Gage.—1. The weather gage is the sooner clear of smoke; and of course, that line can better observe the signals which are spread than the ships to leeward can, which must have the continuance of both its own smoke and that of the enemy longer. 2. If the weather ships are more in number than the enemy's, they can detach some from their squadron, which bearing down upon the rear of the enemy, must infallibly throw them into disorder. 3. The fireships of the weather line can, when they are ordered, more easily bear down upon the enemy, than those of the lee can ply to windward, which can never be done against a line in action; but the weather fireships can bear down against all the resistance that can be made by the enemy.

Advantages of the Lee Line.—1. If one, two, or more of the ships to windward should be disabled, they must inevitably drive to leeward, and become a prey to the enemy. 2. The ships of the lee line can more readily bear away before the wind, and have their places supplied by ships from the corps-de-reserve, in case of being disabled, or meeting with any disaster. 3. The line to leeward can keep their ports longer open in a strong wind with a high sea, when those to windward in all probability may be obliged to shut the ports of their lower tier

of guns, to prevent the water from rushing in between decks, which may be attended with the most fatal consequences. 4. The lee line can more easily observe the men on the decks of the ships to windward, as they heel, and when the smoke does not intercept their sight; at which time the marines and topmen may easily take aim at and destroy them with muskets and carabines.

The disadvantages of the weather line sometimes counter-balance the advantages above recited, viz: 1. If the sea is rough, and the wind boisterous, it cannot readily fight with the lower deck guns. 2. The weather line cannot decline the action without the dangerous expedient of forcing through the enemy's line, and if it keeps the wind, the lee line may enclose and totally destroy it, especially if it is inferior in numbers to the latter; or if the ships thereof are in a bad condition, for it then can find no other resource but in the dexterity of its manœuvres, unless it is favoured by the wind, or any oversight of the enemy. 3. The disabled ships of the weather-line must tack, to avoid falling into the enemy's fleet; and if they are much shattered, they may be altogether separated, particularly if they are in the rear of the line.

The defects of the Lee Line are.—1. It cannot decide the time and distance of the battle, which may commence before it is sufficiently formed, and it will perhaps be attacked by an enemy who bears away upon it in regular order. 2. It suffers much inconvenience from the fire and smoke of the weather-line, as remarked in the advantages of the weather line (b.). It cannot easily break the enemy's line with its fire-ships, which are slowly and with difficulty conveyed to windward. On the contrary, the fire-ships of the weather line have a considerable advantage (8.)

The line of a fleet, which has abundance of capital ships, need not be so much enclosed as that of an enemy who has fewer. An open line will, on many occasions, work more easily than one which is more enclosed; and if it is less numerous, the movements thereof are more expeditious, the signals better attended to, the general orders more exactly observed, and the ships less liable to be separated. Hence it will be less embarrassed by a change of wind, and order will be sooner re-established. A less numerous line will more readily approach or escape from an enemy or an hostile shore, and finally, when cruising in a smaller space, it will notice so much contracted. It must be remarked, that the admiral's ship attentively preserves her station in the centre of the line; for if the commander in chief should give way to the caprice or inattention of any of those under his direction, it would introduce an endless disorder into his squadron.

LINE, is also the general appellation of a number of small ropes in a ship, as

Concluding Line, a small rope which is hitched to the middle of every step of a stern ladder.—*Deep Sea Line*, a long line, marked at every five fathoms with small strands of line knotted. It is used with the deep-sea lead.—*Fishing Line*, a particular kind of line generally used for fishing.—*Hand Line*, a line about 20 fathoms long, marked with black leather, white rag, and red bunting, at different distances. It is made fast to a hand lead, and used to determine the depth of water in going in or out of harbour, river, channel, &c.—*Hauling Line*, any rope let down out of a top, &c. to haul up some light body by hand.—*Knave Line*, a rope fastened to the cross-trees, under the main or fore top, whence it comes down by the ties to the ram-head, and there it is reeved through a piece of wood of about two feet long, and so is brought to the ship's side, and there hauled up taught to the rails.—*Life-Line*, a rope occasionally extended in several situations for persons to lay hold of, to prevent their falling.—*Naval-Line*, a rope depending from the heads of the main and fore masts, and fastened to the middle of the truss, to keep it up whilst the yard is being swayed up.—*Spilling Lines*, ropes fixed occasionally to the square-ails, particularly the main and fore courses of a ship in tempestuous weather, for reefing or furling them more conveniently; they are reeved through blocks upon the yard, whence leading round the sail, they are fastened behind to the yard, so that the sail is by their efforts very closely confined.—*White-Line*, implies that which has not been tarred, in contradistinction to tarred line.—*Mar-Line*, is a particular kind of small line, composed of two strands very little twisted; there is both tarred and white mar-line.

LINEN, in Commerce, a well-known kind of cloth, chiefly made of flax. Linen was not worn by the Jews, Greeks, or Romans, as any part of their ordinary dress. Under-tresses of a finer texture supplied the place of shirts: hence the occasion for frequent bathing. Alexander Severus was the first emperor who wore a shirt: but the use of so necessary a garment did not become common till long after him. In Egypt, indeed, the linen manufacture appears to have been very early; for even in Joseph's time it had risen to a considerable height. From the Egyptians the knowledge of it proceeded probably to the Greeks, and from them to the Romans. Even at this day, the flax is imported among us from the eastern nations; the western kind being merely a degenerate species of it. In order to succeed in the linen manufacture, one set of people should be confined to the ploughing and preparing the soil, sowing and covering the seed, to the weeding, pulling, rippling, and taking care of the new seed; and watering and dressing the flax till it is lodged at home: others should be concerned in the drying, breaking, scutching, and hackling the flax; to fit it for the spinners; and others in spinning and reeling it, to fit it for the weaver: others should be concerned in taking due care of the weaving, bleaching, beetling, and finishing the cloth for the market. It is reasonable to believe, that if these several branches of the manufacture were carried on by distinct dealers in Scotland and Ireland, where our home-made linens are manufactured, the several parts would be better executed, and the whole would be afforded cheaper, and with greater profit.

Staining of Linen.—Linen receives a black colour with much more difficulty than woollen or cotton. The black struck on linen with common vitriol and galls, or logwood, is very perishable, and soon washes out. Instead of vitriol, a solution of iron in sour strong beer is to be made use of. This is well known to all the calico-printers; and by the use of this, which they call their iron-liquor, and madder root, are the blacks and purples made, which we see on the common printed linens. The method of making this iron-liquor is as follows: A quantity of iron is put into the sour strong beer; and to promote the dissolution of the metal, the whole is occasionally well stirred, the liquor occasionally drawn off, and the rust beat from the iron, after which the liquor is poured over again. A length of time is required to make the impregnation perfect; the solution being reckoned unfit for use, till it has stood at least a twelvemonth. This solution stains the linen of a yellow, and different shades of buff-colour; and is the only known substance by which these colours can be fixed in linen. The cloth stained deep with the iron-liquor, and afterwards boiled with madder, without any other addition, becomes of the dark colour which we see on printed linens and cottons; which, if not a perfect black, has a very near resemblance to it. Others are stained paler, with the same liquor diluted with water, and come out purple. Linen may also be stained of a durable purple by means of a solution of gold in aqua regia. The solution for this purpose should be as fully saturated as possible; it should be diluted with three times its quantity of water; and if the colour is required deep, the piece, when dry, must be repeatedly moistened with it. The colour does not take place till a considerable time, sometimes several days, after the liquor has been applied: to hasten its appearance, the subject should be exposed to the sun and free air, and occasionally removed to a moist place, or moistened with water. When solution of gold in aqua regia is soaked up in linen cloths, the metal may be recovered by drying and burning them.

Fossil Linen, is a kind of amianthus, which consists of flexible, parallel, soft fibres, and which has been celebrated for the use to which it has been applied, of being woven, and forming an incombustible cloth. Paper also, and wicks for lamps, have been made of it.

LINIMENT, in Pharmacy, a composition of a consistence somewhat thinner than any unguent, and thicker than an oil.

LINSTOCK, a staff about three feet long, having a sharp point at one end, and a sort of fork or crotch in the other; the latter serves to contain a lighted match, and by the former, the linstock is occasionally stuck in the deck in an upright position. It is frequently used in small vessels in an engagement, where there is commonly one fixed between every two guns, by which the match is always kept dry and ready for firing.

LINT, in Surgery, is the scrapings of fine linen, used by surgeons in dressing wounds. It is made into various forms, which acquire different names according to the difference of the figures. Lint, made up in an oval or orbicular form, is called a pledgit; if in a cylindrical form, or in shape of a date or olive stone, it is called a dossil. These different forms of lint are required for many purposes; as, 1. To stop blood in fresh wounds, by filling them up with dry lint before the application of a bandage: though, if scraped lint be not at hand, a piece of fine linen may be torn into small rags, and applied in the same manner. In very large hæmorrhages, the lint or rags should be first dipped in some styptic liquor, as alcohol, or oil of turpentine; or sprinkled with some styptic powder. 2. To agglutinate or heal wounds; to which end, lint is very serviceable, if spread with some digestive ointment, balsam, or vulnerary liquor. 3. In drying up wounds and ulcers, and forwarding the formation of a cicatrix. 4. In keeping the lips of wounds at a proper distance, that they may not hastily unite before the bottom is well digested and healed. 5. They are highly necessary to preserve wounds from the injuries of the air.—Surgeons of former ages used compresses of sponge, wool, feathers, or cotton, linen being less plentiful than in later times: but lint is far preferable to all these, and is at present universally used.

LINUM USITATISSIMUM. *FLAX*, or *Lint Seed*.—Is grown for the purpose of making cloth, and has been considered a very profitable crop. The culture and management is similar to that of hemp, and the seeds are in great demand for pressing. Linseed oil, which it produces, is much used by painters, and is the only vegetable oil that is found fit for such purposes in general. The seeds are of several uses to the farmer; a tea is made of it, and mixed with skimmed milk, for fattening house-lambs and calves. Oxen are often fattened on the seed itself; but the cakes, after the oil is expressed, are a very common and most excellent article for fattening both black cattle and sheep. These are sold at from £10 to £16 per thousand. It will require three bushels of flax-seed for one acre, as it must be sown thick on the land. Linseed cake has been used also for manure; and I have seen fine crops of turnips, where it has been powdered, and sown in the drills with the seed.

LIQUORICE. The glycyrrhiza, or common liquorice shrub, has a long, thick, creeping root, striking several feet deep into the ground; an upright, firm, herbaceous, annual stalk, three or four feet high, garnished with winged leaves, of four or five pair of oval lobes, terminated by an odd one; and from the axillas, erect spikes of pale blue flowers in July, succeeded by short smooth pods. The root of this plant is the useful part, being replete with a sweet, balsamic, pectoral juice, which is either extracted, or the wood sold in substance. It is much used in all compositions for coughs, and disorders of the stomach; but by far the greatest quantity is used by brewers. The common liquorice is cultivated in most countries of Europe, for the sake of its root; but in Spain and Italy, and particularly in Sicily and Calabria, it makes a considerable article of commerce with this country. Liquorice also grows in great abundance in the Levant; and vast quantities of it are consumed there, in making a decoction which is drunk cold in the summer, in the manner of sherbet. To prepare liquorice, the roots are boiled a long time in water, till the fluid has got a deep yellow tincture; and the water at length evaporated till the remains acquire a consistency, when they are formed into sticks, which are packed up with bay leaves, in the same order as we receive them. The boiling requires the utmost care and precaution, as the juice takes an unpleasant smell and flavour, if burnt in the least degree.

LIST, CIVIL, in the British polity. The expenses defrayed by the civil list are those that in any shape relate to civil government; as, the expenses of the household; all salaries to officers of state, to the judges, and every one of the king's servants; the appointments of foreign ambassadors; the maintenance of the queen and royal family; the king's private expenses, or privy purse; and other very numerous out-goings, as secret-service money, pensions, and other bounties; which sometimes have so far exceeded the revenues appointed for that purpose, that application has been made to parliament to discharge the debts contracted on the civil list.

To LIST, or **ENLIST SOLDIERS**, to retain and enroll men as soldiers, either as volunteers, or by a kind of compulsion. Persons listed, must be carried within four days, but not sooner than twenty-four hours after, before the next justice of peace of any county, riding, city, or place, or chief magistrate of any city or town corporate, (not being an officer in the army,) and if, before such justice or magistrate, they dissent from such enlisting, and return the enlisting money, and also twenty shillings in lieu of all charges expended on them, they are to be discharged. But persons refusing or neglecting to return and pay such money within twenty-four hours, shall be deemed as duly listed as if they had assented thereto before the proper magistrate; and they shall, in that case, be obliged to take the oath, or, upon refusal, they shall be confined by the officer who listed them till they do take it.

LIST, in Commerce, the border of cloth or stuff; serving not only to shew their quality, but to preserve them from being torn in the operations of fulling, dyeing, &c. List is used on various occasions; but chiefly by gardeners, for securing their wall trees.

LIST, in Architecture, a little square moulding, otherwise called a fillet, listel, &c. See ARCHITECTURE.

LIST, is also used to signify the enclosed field or ground wherein the ancient knights held their jousts and tournaments. It was so called, as being hemmed round with pales, barriers, or stakes, as with a list. Some of these were double, one for each cavalier; which kept them apart, so that they could not come nearer each other than a spear's length. See JUST, TOURNAMENT, DUEL, &c.

LIST, implies an inclination to one side, as, The ship has a list to port, i. e. is depressed more in the water on that side.

LITANY, a solemn form of supplication to God, in which the priest utters some things fit to be prayed for, and the people join in their intercession, saying, "We beseech thee to hear us good Lord," &c. The word comes from the Greek "supplication." Before the last review of the common prayer, the litany was a distinct service by itself, and used some time after the morning prayer was over; at present it is made one office with the morning service, being ordered to be read after the third collect for grace, instead of the intercessional prayers in the daily service.

LITHOGRAPHY. Lithography, or the art of taking impressions from drawings or writings made on stone, is quite a modern invention. It, unlike letter-press or copperplate printing, which are altogether mechanical processes, depends entirely upon chemical principles, and has therefore been called in Germany, chemical printing. The principles on which it is founded are, first, the quality which a compact granular limestone has of imbibing grease or moisture; and secondly, the decided antipathy of grease and water for each other. A drawing is made on the stone, either with ink or with a crayon of a greasy composition; it is then washed over with water, which sinks into those portions of the stone which are untouched with the grease of the drawing. A cylindrical roller, charged with printing ink, is then passed all over the stone; and, while the drawing receives the ink, the rest of the stone is preserved from it by the water, on account of the greasy nature of the ink.

This useful art was invented by mere accident. Alois Senefelder, the son of a performer at the theatre royal, Munich, a student of jurisprudence in the university of Ingoldstadt, after the death of his father, took likewise to the stage; but, being unsuccessful in his pursuit of it, he afterwards became an author. Poverty was indeed, in him, the mother of invention; for being too poor to publish his works, he tried various plans, with copperplates and compositions, as substitutes for letter-press, that he might thus become his own printer. In the course of his experiments he found that a composition of soap, wax, and lamp black, formed an excellent ink for writing with on plates; as, when dry, it became firm and hard, and resisted aquafortis. He wanted facility, however, in writing backwards on the plates, and that he might practise this at less expense, he procured some pieces of Kilheim stone, as a cheap material, on which, after polishing their surfaces, he might practise. Having been desired by his mother to take a list of some linen about to be sent to be washed, and having no paper at hand,

substance it is softer. After being completely melted and mixed with the black, it should be run on a marble slab, and a heavy weight placed above it, in order to press it.

After very careful management, the ink will be sometimes found defective; this, however, must proceed from something being wrong with the ingredients, or the manner of their preparation; but, as it is impossible to prevent imperfections, it will be as well to mention a few of those which most commonly occur, with the remedies to be used to remove them.

Defects of the Ink, and Remedies to be used.—1st. The ink will at times be found insoluble. The proper remedy, in this case, is to add more soap, in the same manner it was first added. Although the ingredients are to be melted over a fire, in order to have the additional soap mixed with them, they must not be allowed to take fire, as was the case when the soap was first added. 2d. It is sometimes too soft, and attaches itself to the fingers. When this happens, it must again be put into the saucepan, and burned till it gets to a proper consistence.

3d. We find a defect of almost all inks to be, that, some time after dissolving them in water, they become thick and slimy, and require a continual addition of water before we are enabled to draw with it. This is solely owing to its not being sufficiently burnt; and of course the only remedy is, as in the former case, to burn it more. 4th. If the ink is not compact, but full of bubbles, it has been cast too hot on the marble slab. It must therefore be re-melted, cast again when it is less hot, and a heavier weight must be placed upon it. 5th. On other occasions the ink will be found to have no tenacity, and seem to be composed of scorias. When this is the case, it has been either too much burnt, or contains too much black; in either case, add equal portions of wax and soap, and melt it again over a slow fire.

The only other ink we have mentioned, as being necessary in lithographic drawing or printing, is

Ink for making Transfers.—This ink is composed of the very same materials as the ink for writing or drawing; but they must be less burned. It will thus be softer, and it must also be afterwards melted and mixed with a little more wax and thick varnish, such as those we shall mention when we come to speak of the printing ink.

Lithographic Chalk.—Besides the inks, we have already mentioned that chalks are used for drawing. Good lithographic chalk ought to have all the qualities of a good drawing crayon. It should be even in texture, and should carry a good point. The best proportions for its composition are the following: an ounce and a half of common soap; tallow two ounces; virgin wax two and a half ounces; shell lac one ounce. The rest of the process is the same as in making the ink. Less black should be mixed with the chalk than with the ink, its only use being to colour the drawing, that the artist may see the lines he traces. When the whole is well mixed, it should be poured into a mould, and very strongly pressed, to prevent any bubbles which would make the texture irregular. Now that we have described the preparation of the stone, and of the inks and chalk necessary for drawing, we must next proceed to notice the

Mode of Drawing.—Previous to drawing or writing, the stone must be well wiped with a clean dry cloth. The ink is rubbed with warm water like Indian ink, and must be used on the polished stone, while the chalk, which would not hold upon it, must be used on the ground stone. A gradation of tints, in drawing with the ink, can easily be obtained by merely varying the thickness of the line, and the distance at which they are placed apart; for the line traced by the ink being sound and unbroken throughout, receives the printing all over. It is thus plain that no advantage can be obtained by diluting the ink for the purpose of varying the tints of the lines, and the great object of the artist ought therefore to be, to have his ink of the proper consistency, which will stand best throughout the process of printing. A consistency a little stronger than common writing ink will be sufficient for this purpose.

When the chalk is to be used, the ground stone must be cleaned of all dust, and it is then drawn upon with the chalk in the same manner as crayons are used on paper. It is proper that the strength of the tint which is wished should be given at once, as the surface of the stone is altered by receiving the

chalk, and it will not receive new lines equally well; and the strength of the tint will be regulated by the pressure of the hand. Nothing but practice ever gives the necessary command of the material, which undoubtedly does not work quite like the common crayon, there being great difficulty in keeping a good point. There is likewise considerable trouble in obtaining the finer tints sound in the impression; and in order to obtain the lighter tints properly, it will be necessary to put the chalk in a rest, as the metal port crayon is too heavy to draw them, even although there is no pressure of the hand used. Several pieces of chalk should be prepared, to use in succession, as the warmth of the hand softens it. It is useful to cut the chalk to the form of a wedge rather than a point, as it is less likely to bend in that form. Small portions sometimes break off during the drawing; these must be carefully removed with a brush.

We now proceed to describe the press and rollers used, with the manner of printing. That given in the engravings is certainly the best we have ever seen, although there are different forms in use.

Fig. 1, is a side elevation of the press, with the scraper partly down. Fig. 2, a cross section through the middle. Fig. 3, a horizontal plan of the upper part. Fig. 4, detail of the manner in which the scraper is held down during the impression.

Fig. 5, end elevation of the press. Fig. 6, to explain the manner in which the centre of motion of the scraper is raised and lowered.

The press consists of a strong frame, having on the upper part a platten or bed, *a*, to receive the stone, and which is moved along grooves in the upper part of the frame by means of a star-wheel *b*, to the axis of which is fixed a cylinder *c*. On this cylinder the straps *d, d*, are gathered, which work over the pulleys *e*, fixed to the bed. When the stone is placed on the bed, and ready for the impression, the frisket, or cover, *f*, of the bed, is brought down from the position marked by the dotted outline in fig. 1, and shut over the stone, as shown in the same figure. This cover consists of a strong piece of calf's skin, stretched by screws with nuts and hooks, which catch hold of an iron rod sewed along one end of the skin. The other end of it is fixed to the opposite end of the frame. (See fig. 3.) The cover is fixed to the bed by hinges, *g*, which can be screwed at different heights, according to the thickness of the stones. When the cover is opened, it rests against the frame *A*, which can be adjusted to different heights. (See figs. 1 and 5.)

The cross piece *i*, having the scraper *k* fixed in it, is now brought down, and the catches *l* lock into the upper part of the piece *n*, sliding between the grooved upright *m*. This is shown more in detail in fig. 4; the upper part where the catches lock, is of iron, and has a joint and handle to pull it out when the scraper is to be unlocked. A spring *o*, keeps it generally in an upright position to be ready to hold the catches *l, l*. When the scraper is locked down, the printer sets his foot on the treadle *p*, of the lever, which presses the scraper with great power on the stone. The pressure is by a double lever, having a connecting rod *q*, which can be adjusted so as to bring the upper arm *r* nearer to the treadle, when an increase of pressure is required, or a thinner stone is placed on the bed, which makes it necessary to bring the scraper lower down. The arm *r* passes through an iron frame on the sliding piece *n*, and thus brings it down when the treadle is depressed. The hook *s* holds down the treadle during the impression.

The star wheel *b* is now turned round, and by this motion the bed is drawn under the scraper, and the impression is taken. The bed passes over a roller *t*, which is placed with its centre directly under the scraper. (See fig. 2.) As the stones are not always of the same thickness, the scraper must be brought to different heights. Fig. 6, shows an adjusting screw for the purpose of regulating the end farthest from the catches, there being a sliding piece between the grooved uprights *u*, in which the centre is fixed, on which the cross piece *i* turns. The iron *v*, fig. 2, stops the cross piece and scraper from falling back. When the bed has been drawn out, the printer releases the treadle, which is raised up by the balance weight *w*, and the scraper being unlocked and thrown back, the bed is drawn to its first position by the weight *x*.

As the surface of the stone is not always quite parallel to the bed, a simple contrivance has been adopted, to allow a self-adjustment of the scraper, which is allowed to turn on the centre, and pressed down by a spring acting on each end, but yielding if necessary at either. It is shown by the dotted lines in fig. 2. The screw *y* presses the scraper lower, or raises it, if required. The scrapers are made of beech wood.

The Roller.—The roller for inking the drawing is of the form represented in fig. 7. The length may vary, but it ought to be full four inches in diameter. It is covered with flannel, rolled tightly three or four times round, and nailed at the ends. It is then covered with a stretched calf-skin, fitting quite tight. The seam must be made neatly with the boot-maker's closing stitch. The ends of the leather are gathered with a string, and tied round the projecting ends of the roller. Loose handles, *A, A*, made of thick leather, are put on these ends when it is used. The leather must be put on the roller with the rough side outwards.

Printing Ink.—The printing ink is composed, as other printing inks are, of oil, varnish, and very fine lamp-black, well mixed together. To prepare the varnish, a saucepan is about half filled with pure linseed oil, and heated over a fire till it ignites from the flame of a piece of burning paper. It should then be allowed to burn till it is reduced to the degree required; and if, during the operation, there appears danger

of its boiling over, it must be immediately taken off the fire, and the cover, which ought to fit quite close on the saucepan, must be put on to extinguish the flame. This is to prevent accidents; and the operator cannot be sufficiently cautioned against the danger attending the burning of the varnish, which ought never to be performed in a room with a boarded floor, or indeed in any part of a house. Wet sacks are the best things to put out the flame in case of accident.

Several inks must be prepared, differing in the degree of viscosity, or thickness of the varnish from which they are made, and the quantity of black mixed with them. The longer the oil is burned, the thicker the varnish becomes. The thinnest varnish is burned till it has lost nearly one-fourth of its volume; the next, till it is reduced one-third; the thickest, till it is reduced one-half.

These directions are to be considered as very general ones; and the state of the varnish is best judged of during the burning, by taking out some with a spoon, and letting a drop fall on a cold earthenware plate, and trying its degree of viscosity with the finger. The thinnest sort should be like common honey, the other should draw out in strings, which will be longer as the varnish is thicker. The thickest will draw out in strings two or three feet long. It is quite essential to have the oil pure, and the saucepan perfectly clean, and to keep the varnish in clean close jars in a cool place. It is best not to make the varnish long before it is wanted; for if any decomposition takes place in it, the drawing will be spoiled by the printing ink.

The black is mixed with the varnish on a grinding stone with a muller, in small successive quantities, care being taken that the first portion of black is equally mixed with the varnish before a second is added. In the thickest inks this requires considerable labour. By mixing the varnishes together, any degree of stiffness of the ink may be obtained; and by putting more or less black, its thickness is regulated.

The printer must always have by him several small pots, each containing a different printing ink, to be used as occasion requires. A small quantity, not more than the size of a hazel nut, should be used at a time, for it is desirable to charge the roller with as small a quantity as possible. It must be worked well on the colour table with the roller in all directions, that it may be equally distributed all over the roller. Ink drawings are generally printed with a stiffer ink than chalk drawings.

Preparation of the Stone for Printing.—The drawing being finished on the stone as before described, is sent to the lithographic printer, on whose knowledge of his art the success of the impressions entirely depends. The first process is to etch the drawing, as it is called. This is done by placing the stone obliquely on one edge over a trough, and pouring over it very dilute nitric acid. It is poured on the upper part of the stone, and runs down all over the surface. The stone is then turned, and placed on the opposite edge, and the etching water, being collected from the trough, is again poured over it in the same manner. The degree of strength, which is little more than one per cent. of acid, should be such as to produce a very slight effervescence; after the etching water has lain on the stone for a second or two, its strength must vary according to the heat of the atmosphere, and the degree of fineness of the drawing. It is desirable to pass the etching water two or three times over the darkest parts of the drawing, as they require more etching than the lighter tints. Some stones also, and different chalks, require different degrees of strength of the acid, and experience alone can guide the lithographer in his practice on this point. Chalk drawings require weaker acid than the ink.

The stone is now carefully washed, by pouring clean rain water over it, and afterwards with gum water: and, when not too wet, the roller, charged with printing ink, is rolled over it in both directions—sideways, and from top to bottom—till the drawing takes the ink. It is then well covered over with a solution of gum-arabic in water, of about the consistency of oil. This is allowed to dry, and preserves the drawing from any alteration, as the lines cannot spread, in consequence of the pores of the stone being filled with the gum. After the etching it is desirable to leave the stone for a day, and best not to leave it more than a week before it is printed from. In some establishments a few proofs are taken immediately after the drawing is etched, but it is better not to do so.

The operation of the etching requires great nicety, and must be done quickly. If the drawing is etched too strongly, the fine tints disappear; if too weak, the printing ink mixes with the darker parts, and the drawing runs into blots. A soft stone requires weaker acid than a hard one, if they are equally pure in quality. The differences in the composition of the stone also require differences in the strength of the etching water, so that no strict rules can be given. The effect of the etching is, first, to take away the alkali mixed with the drawing chalk or ink, which would make the drawing liable to be affected by the water; and, secondly, to make the stone refuse more decidedly to take any grease. The gum assists in this latter purpose, and is quite essential to the perfect preparation of the surface of the stone.

Printing.—When the intention is to print from the stone, it is placed upon the platten or bed of the press, and a proper sized scraper for the printing is adjusted to the surface of the stone. Rain water is then sprinkled over the gum on the stone, which being dissolved gradually, and a wet sponge passed lightly over it all, the printer works the ink which is on the colour table placed beside him, with the roller, in all directions, until it is equally and thinly spread all over the roller. The roller is then passed over the whole stone, care being taken that the whole drawing receives a due portion of the ink, and this must be done by giving the roller an equal motion and pressure, which will of course require to be increased, if it is perceived that the drawing does not receive the ink readily. When the drawing is first used, it will not receive the ink so readily as it will afterwards do; and it is frequently necessary to wet the stone, and roll it several times, before it will take the ink easily. When the drawing once takes the ink readily, care must be taken not to wet the stone too much. Indeed, the less dampness the better, provided there is sufficient to prevent the stone from taking the ink where there is no drawing. After the drawing is thus rolled in, the sheet of paper is placed on the stone, and the impression taken in the manner described in the account of the Press. When, after the impression, the paper is taken up, the stone appears dry, the moisture having been imbibed by the paper; it must, therefore, be wetted with a sponge, and again rolled in with ink, the roller having been well worked on the colour-table before being applied.

During the printing, some gum must always remain on the stone, although it will not be visible, otherwise the ink will be received on the stone as well as on the drawing, and the drawing spoiled. So that if by too much wetting, or by rubbing too hard with the sponge, the gum is entirely removed, some fresh gum water must be laid on. If the stone has in the first instance been laid by with too small a quantity of gum, and the ink stains the stone on being first applied to it, gum-water must be used to clamp the stone, instead of pure water. Sometimes, however, this may arise from the printing ink being too thin, as will afterwards appear. If some spots on the stone take the printing ink, notwithstanding the above precautions, some strong acid must be applied to them with a brush, and, after this is washed off, a little gum-water is dropped on the place. A steel point is here frequently necessary to take off the spots of ink.

The edges of the stone are very apt to soil, and generally require to be washed with an old sponge or rag after the rolling in. They must also frequently have an application of arid and gum, and sometimes must be rubbed with pumice stone. If an ink is too thin, and formed of a varnish not sufficiently burned, it will soil the stone, notwithstanding the proper precautions are taken of wetting the stone, and preparing it properly with acid and gum; and if on the other hand the ink is too thick, it will tear the lighter tints of the chalk from the stone, and thus destroy the drawing. The consideration of these circumstances leads at once to the

Principles of the Printing.—These accidents arise at the extreme points of the scale at which the printing inks can be used, for it is evident that the only inks which can be employed are those which are between these points; that is, thicker than that which soils the stone, and at the same time thinner than that which takes up the drawing. Lithographers are sometimes unable to print in very hot weather, the reason of which may be deduced from the above. Any increase of temperature

will diminish the consistency of the printing ink; the stone will therefore soil with an ink which could be safely used at a lower temperature; hence a stiffer ink must be used. Now, if the temperature should increase so much that the stone will soil with any ink at all less thick than that which will take up the drawing, it is evident that the printing must cease till a cooler temperature can be obtained; for as the drawing chalk is affected equally with the printing ink, the same ink will tear up the drawing at the different degrees of temperature. This, though it sometimes occurs, is a rare case; but it shews that it is desirable to draw with a chalk or ink of less fatness in summer than in winter; and also, that if the printing room is in winter artificially heated, pains should be taken to regulate the heat as equally as possible.

Other Difficulties in Printing, not referable to the above general principle.—If the pressure of the scraper is too weak, the ink will not be given off to the paper in the impression, although the drawing has been properly charged with it. Defects will also appear from the scraper being notched, or not correctly adjusted, or from any unevenness in the leather or paper.

After printing a considerable number of impressions, it sometimes happens that the drawing takes the ink in dark spots in different parts. This arises from the printing ink becoming too strongly united with the chalk or ink of the drawing, and, if the printing is continued, the drawing will be spoiled. The reason of this is easily ascertained. The printing ink readily unites with the drawing, and, being of a thinner consistency, it will, by repeated applications, accumulate on the lines of the drawing, soften them, and make them spread. In this case it is necessary to stop the printing, and let the stone rest for a day or two, for the drawing to recover its proper degree of hardness. If the drawing should run smutty from any of the causes before enumerated, the following

Mixture for Cleaning the Drawing while Printing must be used. Take equal parts of water, spirits of turpentine, and oil of olives, and shake them well together in a glass vial, until the mixture froths; wet the stone, and throw this froth upon it, and rub it gently with a soft sponge. The printing ink will be dissolved, and the whole drawing also will disappear, though, on a close examination, it can be distinguished in faint white lines. On rolling it again with printing ink, the drawing will gradually reappear as clear as at first.

Bleached Paper unfit for Lithographic Printing.—Accidents sometimes occur in the printing from the qualities of the paper. If the paper have been made from rags which have been bleached with oxymuriatic acid, the drawing will be incurably spoiled after thirty impressions. Chinese paper has sometimes a strong taste of alum; this is so fatal as sometimes to spoil the drawing after the first impression. When the stone is to be laid by after printing, in order that it may be used again at a future period, the drawing must be rolled in with a

Preserving Ink,—as the printing inks would, when dry, become so hard, that the drawing would not take fresh printing ink freely. The following is the composition of the preserving ink. Two parts of thick varnish of linseed oil, four parts of tallow; one part of Venetian turpentine, and one part of wax. These must be melted together, then four parts of lamp black, very carefully and gradually mixed with it, and it must be preserved for use in a close tin box. Very good effects are produced in lithographic prints, by

Printing from two or more Stones—with different coloured inks. This is managed by preparing a composition of two parts of wax, one of soap, and a little vermilion. Melt them in a saucepan, and cast them into sticks. This must be rubbed up with a little water, to the thickness of cream, and applied to the surface of a polished stone. An impression is taken in the common way from a drawing, and applied to a stone, prepared in this manner, and passed through the press, taking care to mark, by means of this impression, two points in the margin corresponding on each of the stones. The artist having thus, on the second stone, an impression from the first drawing to guide him, scrapes away the parts which he wishes to remain white in the finished impression. The stone must now be etched with acid stronger than the common etching water, having one part of acid to twenty of water. The whole is then washed off with turpentine. This plan is generally used to print a mid-

ation for peculiar privileges: but are much more commonly advanced by individuals on a certain interest being allowed either for a term of years, or until the principal shall be repaid; the capital stock being transferable.

LOBE, in Anatomy, any fleshy protuberant part, as the lobes of the lungs, the lobes of the ears, &c.

LOBELIA, *Cardinal-flower*, a genus of plants belonging to the syngonisia class, and in the general method ranking under the 20th order, Campanaceæ.

LOBBY, in Architecture, is a small hall, or waiting room: it is also an entrance into a principal apartment, where there is a considerable space between that and a portico or vestibule, and the length or dimensions will not allow it to be considered as a vestibule or an anti-room.

LOCK, a well known instrument used for fastening doors, chests, &c. generally opened by a key. The lock is reckoned the master piece in smithery; a great deal of art and dexterity being required in contriving and varying the wards, springs, bolts, &c. and adjusting them to the places where they are to be used, and to the several occasions of using them. From the various structure of locks, accommodated to their different intentions, they acquire various names. Those placed on outer doors are called *work locks*; those on chamber-doors, *spring-locks*; those on trunks, *trunk-locks*, *padlocks*, &c.—Of these the spring-lock is the most considerable, both for its frequency and the curiosity of its structure. Its principal parts are, the main-plate, the copper-plate, and the pin-hole: to the main-plate belong the key-hole, top-hook, cross-wards, bolt-toe, or bolt-knob, draw-back-spring tumbler, pin of the tumbler, and the staples; to the cover-plate belong the pin, main-ward, cross ward, step-ward, or dap-ward; to the pin hole belong the hook-ward, main cross-ward, shank, the pot or bread bow-ward, and bit.

The principle on which all locks depend is the application of a lever to an interior bolt, by means of a communication from without; so that, by means of the latter, the lever acts upon the bolt, and moves it in such a manner as to secure the lid or door from being opened by any pull or push from without. The security of locks in general therefore depends on the number of impediments we can interpose betwixt the lever (the key) and the bolt which secures the door; and these impediments are well known by the name of *wards*, the number and intricacy of which alone are supposed to distinguish a good lock from a bad one. If these wards, however, do not in an effectual manner preclude the access of all other instruments besides the proper key, it is still possible for a mechanic of equal skill with the lockmaker to open it without the key, and thus to elude the labour of the other. The excellence of locks consists in the security they afford; and as numberless schemes are continually brought forward by designing men, to elude every contrivance of the most ingenious mechanics, the invention of a durable lock, so constructed as to render it impossible for any person to open it without its proper key, has ever been an object of considerable importance.

In the year 1784 the Society for the Encouragement of Arts, &c. conferred their silver medal on Mr. Taylor, of Petworth, for his improvement on the latch or spring-bolts of common locks. This is effected by simply reversing the tumbler, so that its curved side acts against two studs fixed on the tail of the latch, and thrusts back the latter with ease; whether the knob be turned to the right or to the left, when the lock is opened. Mr. Taylor has also behind the tail of the latch fixed a guide containing a groove, in which runs a small *friction-wheel*, that serves to keep the latch in its direct situation, and at the same time to diminish its friction: the arms of his tumbler are somewhat contracted, in order that the latch or spring bolt may move with great facility. By this construction, the parts of the tumbler and latch, which are in contact, move in a line, so that they pass over the greatest space, and under the smallest angle; and the lock itself may be constantly used for several years without requiring the application of oil. Various patents have been obtained for the construction of locks, so as to prevent the possibility of picking them: the principal of these is Bramah's.

Chubb's Patent Detector Lock.—The following drawing will give our readers a full insight into the peculiarities of Chubb's celebrated Detector Lock. A A a, the bolt; b, the square pin

of the bolt; c c the detector moving on the centre d; f the detector spring; g four tumblers moving separately on the centre h, shown lifted by the key to the exact position, for the square pin b of the bolt to pass in unlocking. Should one or more of the tumblers be lifted by a pick, or false key, in the least degree beyond their present position, the detector e x, being thus overlifted, will, by the angle of the spring f pressing on the opposite side of the angle of the detector, force its hook into the notch a of the bolt, and be firmly held so, until disengaged by the regulating slide K k in which case, by the introduction of the key, the tumblers are lifted to the regulating

combination, and admit the stud n affixed to the regulating slide, to enter the several grooves in the ends of them; the bevelled end k of this slide, by the same movement, pressing against the hook of the detector, disengages it from the notch a of the bolt.

The merits of this lock, as stated by the ingenious inventor, are, that it possesses, in a much higher degree than any other, the four principal requisites of a good lock, viz. security, simplicity, strength, and durability. Its security is increased beyond calculation, by an improvement which not only renders it impossible to be picked or opened by any false instruments, but also detects the first attempt to open it, thereby preventing those repeated efforts to which even the best locks hitherto invented are exposed. The instant that one or more of the tumblers are lifted beyond the place where the bolt is at liberty to pass, it overlifts the detector, which then hooks the tail of the bolt, prevents it from passing, and thus gives incalculable additional security, (as well as immediate notice, the first time the true key is put into it to open it, that an attempt has been made to pick it,) and renders all farther attempts useless, it being impossible to discover the first combination, in order to disengage the detector, or the second, in order to remove the bolt. Nothing, in short, but the true key can either release the detector from its grasp on the bolt, or open the lock.

The simplicity of its construction, and strength of its parts, are such, that no false key or other instrument introduced into it for the purpose of opening it, can (without great violence) injure it. The keys are small and portable, particularly those for iron doors.

With respect to its durability, it is not liable to be injured by constant use in any length of time; this has been ascertained by an iron-rim lock having been attached to a steam-engine in the dock yard, Portsmouth, (to try the effect of friction,) by which it was locked and unlocked upwards of four hundred and sixty thousand times, without receiving the least injury. The honourable Navy Board lately supplied a considerable number of Chubb's patent detector locks for the use of the Portsmouth dock yard, and being informed that there was a convict on board one of the prison ships at that port, who was notorious for picking locks (being by profession a lock-maker, and who has, till recently, for several years been chiefly employed in

ing a circular shoulder, which shoulder must be rather larger than the shoulder of B. Within this piece, B, must be formed at the shoulder end, a corresponding screw to the one on B. At the other extremity of B a corresponding circular hole is to be made through, to come in contact with the circular hole in B.

The mode in which this additional lock security will operate is as follows:—The piece A is to screw into the centre of piece B, on the side where the shoulder is, which is to be bored through as far as the circular hole in B, with a corresponding screw of A. Then ascertain the thickness of the door to which you mean to apply this machinery; lengthen or shorten the piece A by means of the screw; introduce your cross-piece, A, into the key-hole, or, as may be, through to the inner side of the door; then turn the cross piece transverse to the key-hole, leaving the shoulder of B as close in contact as possible with the key-hole.

The piece C is then to be slid on the shoulder of B, being made sufficiently large to cover the key-hole. The projecting piece D going into the lower part of the key-hole, keeps the transverse position of A from being displaced. E is then to be screwed over B, tight against the plate C, the shoulder of E being rather larger than that of B, so that the shoulder of E may press against that of C.

The two circular corresponding holes in B and E coming in unison, you pass through the bar of your combination lock, or common padlock, as you please, and your key-hole is then secured from a picklock, or introduction of skeleton or false keys. By making the circular holes longitudinally, you may apply two or more combinations or padlocks, in case you wish to make any room or chest a deposit for joint security. Another great advantage to a door that opens externally, having a key-hole and no lock on it, is that, by having a cross piece, as A, with one side of the cross of a proper length, so as to bear against the inner side of the door-post, your door may be securely fastened.

To travellers, and persons travelling about for pleasure, who too often suffer from the insecurity of locks, this apparatus seems particularly worthy of attention. No injury is done by applying it, and it is of such light weight, as to be portable in the pocket. This invention professes to come from a lieutenant of the royal navy; we should have been happy to have added his name, did we know it.

Description of an Instrument for Securing Door and other Locks.—The object of the instrument about to be described, and which is here represented, is to prevent the introduction of a skeleton key, or similar implement, into a lock, for the purpose of opening it. Its parts are as follow: *aa* is a circular plate of stout iron, sufficiently large to cover

the key-hole; *bb* is a cylindrical pipe, which passes perpendicularly through a hole in the centre of the plate *aa*, and is strongly fastened to it by means of the projecting shoulder *cc*; *dd* is a round bar, enclosed in the pipe *bb*; *e* is a small nut riveted to the end of *dd*, for the purpose of turning it; *mm* are two small pieces of iron attached transversely to the cylindrical pipe *bb*, and its enclosed bar *dd* respectively. When the instrument is being introduced into the key-hole, these pieces coincide, or rest longitudinally upon each other (as in fig. 1); but when passed through the lock, they are turned at right angles to each other, by the thumb-nut, or bottom already mentioned, and are, in this situation, firmly inserted cross-wise into each other, by means of a small groove, cut in each of them; *n* (fig. 2) is a front view of these pieces when secured in their place; *f* is a cylindrical

aperture, part of which is in the wire *a*, and part in the shoulder *c*. To this aperture is accurately fitted the transverse bar of a strong combination lock, so complex as to be totally inaccessible to any person except the possessor of its key. While the bars at *m, m*, remain across each other, the instrument cannot be removed out of its place; and hence the security of this lock, for strong boxes, counting-houses, and places of safety.—*Mech. Mag.* 1824.

New Double Door Spring.—The annexed are drawings of a double door spring, invented by Mr. James White, of Laystall-Street, which may be fixed either at top or bottom of the door, and is so contrived that the power of the spring is greatest when the door is shut. It is not liable to get out of repair, and the expense is moderate, not exceeding twenty-two shillings.

In fig. 1, the dotted lines *aa*, show part of the door shut; *b*, the centre on which the door turns; *c*, an arm carrying a friction roller (*d*, fig. 3); *e e*, two levers on which the spring *f*

acts, and thereby holds the door shut; *g*, a stop, which prevents the levers being pushed farther than to the shut door. When the door is shut, the spring *f* acts with half its power on the arm *c*, at full length, but when the door is open as in fig. 2, it acts with about one-sixth of its power on the arm *c*, in a direction which reduces its effect on the door also about one-sixth, whereby the action on the door, when open, is one-eighteenth of the power which holds it shut; but admitting the strength of the spring to have increased by one-half, there then remains a reduction of power equal to one-twelfth of the original quantity. These numbers, however, depend on the proportion of the levers, and on the part where the spring acts.

In figs. 1, and 2, the upper plate by which it is screwed to the floor, is removed, to show the parts; its place is shown by the dotted lines and holes *h h h h*. Fig. 3, a section of the box; *aa*, part of the door shut; *ii*, a brass shoe screwed on the door; the centre *b* is fitted into a square hole, and secured by a screw nut *k*; *l*, a screw which hooks on to the spring *f*, to regulate its power by turning the nut *m*.—*Mech. Mag.* 1824.

Lock, or **Weir**, the general names for all those works of wood or stone made to confine or raise the water of a river: the banks also which are made to divert the course of a river are called by these names in some places. But the term **Lock** is more particularly appropriated to express a kind of canal enclosed between two gates; the upper called by workmen the sluice-gate, and the lower called the flood-gate. These serve in artificial navigations to confine the water, and render the passage of boats easy both in passing up and down the stream.

LOCKER, a kind of box or chest made along the side of a ship, to put on board anything in.—**Shot Lockers**, strong frames of plank near the pump-well in the hold, in which the shot are put.

LOG, a machine used to measure the rate of a ship's velocity through the water. For this purpose, there are several various inventions, but the one most generally used is the following, called the common log. It is a piece of thin board, forming the quadrant of a circle of about six inches radius, and balanced by a small plate of lead nailed on the circular part, so as to swim perpendicular in the water, with the greater part immersed. The log line is fastened to the log by means of two legs, one of which is knotted through a hole at one corner, while the other is attached to a pin fixed in a hole at the other corner, so as to draw out occasionally. The log line being divided into certain spaces, which are in proportion to an equal number of geographical miles, as a half, or quarter minute, is to an hour of time, is wound about a reel.

The whole is employed to measure the ship's head-way in the following manner: the reel being held by one man, and the half-minute glass by another, the mate of the watch fixes the pin, and throws the log over the stern, which, swimming perpendicularly, feels an immediate resistance, and is considered as fixed, the line being slackened over the stern, to prevent the pin coming out. The knots are measured from a mark on the line, at the distance of twelve or fifteen fathoms from the log; the glass is therefore turned at the instant that the mark passes over the stern; and as soon as the sand in the glass has run out, the line is stopped; the water then being on the log dislodges the pin, so that the board now presenting only its edge to the water, is easily drawn aboard. The number of knots and fathoms which had run off at the expiration of the glass, determines the ship's velocity. The half-minute glass and divisions on the line should be frequently measured, to determine any variation in either of them, and to make allowance accordingly.

If the glass runs thirty seconds, the distance between the knots should be 50 feet. When it runs more or less, it should, therefore, be corrected by the following analogy. As 30 is to 50, so is the number of seconds of the glass to the distance between the knots upon the line. As the heat or moisture of the weather has often a considerable effect on the glass, so as to make it run slower or faster, it should be frequently tried by the vibration of a pendulum. As many accidents attend a ship during a day's sailing, such as the variableness of winds, the different quantity of sail carried, &c. it will be necessary to heave the log at every alteration; but if none of these alterations be perceptible, yet it ought to be constantly heaved.

In ships of war and the East Indiamen, it is usual to heave the log once every hour, and in all other vessels once in two hours; and if at any time of the watch the wind has increased or abated in the intervals, so as to affect the ship's velocity, the officer generally makes a suitable allowance for it at the close of the watch.

The inventor of this simple but valuable device is not known, and no mention of it occurs till the year 1607, in an East India voyage published by Purchas. Since that time the term has become quite familiar, both among our own countrymen and foreigners, and there can be no room for apprehension, that a contrivance so useful will ever share the fate of its author.

Log BOARD, two boards shutting together like a book, and divided into several columns, containing the hours of the day and night, the direction of the winds, and the course of the ship, with all the material occurrences that happen during the twenty-four hours, or from noon to noon, together with the latitude by observation. From this table the officers work the ship's way, and compile their journals. The whole being written with chalk, is rubbed out every day at noon.

Log-Book, a book into which the contents of the log-board is daily transcribed at noon, together with every circumstance deserving notice that may happen to the ship, or within her cognizance, either at sea, or in a harbour, &c. The intermediate divisions or watches of a log-book, containing four hours each, are usually signed by the commanding officer thereof, in ships of war or East Indiamen.

Log Line, the line which is fastened to the log.

LOGARITHMS, (the ratio of numbers,) are the indices of the ratio of numbers to one another, or they are a series of numbers in arithmetical progression, answering to another series of numbers in geometrical progression; or, which con-

veys a still more simple and unembarrassed idea of these numbers, they are indices of the powers of a certain radix, which, when involved to the power denoted by the index, is equal to the given number; thus, if $r^x = a$, $r^y = b$, $r^z = c$, then is x the logarithm of a , y the logarithm of b , z the logarithm of c , &c. where r is called the radix of the system, and may be assumed any number at pleasure, unity only excepted. These numbers are of the greatest possible use in almost all arithmetical and trigonometrical operations, because by the help of them multiplication is performed by addition, division by subtraction, involution by multiplication, and evolution by division. To multiply two numbers together, we must take the sum of their logarithms; to divide one number by another, we must subtract the logarithm of the divisor from the logarithm of the dividend. To involve a number to any power, we must multiply the logarithm of the number by the index of the power. And to extract the root of a number, we divide the logarithm of the number by the index of the power whose root is to be extracted; but each of these rules require some additional illustration, which may be seen in any table of logarithms; but before we proceed any farther, let us attend to the history of this brilliant discovery. These properties of the indices of numbers were taken notice of by Stifelius, and even by Archimedes in his work on the numbering of the sands; but it is to Baron Napier, of Merchiston, in Scotland, that we are indebted for the happy idea of applying such numbers to the purposes of arithmetical and trigonometrical calculation, which first appeared in his "Mirifici Logarithmorum Canonis Descriptio," published at Edinburgh in 1614. But of all those who assisted in the construction of logarithmic tables, Briggs is the most conspicuous; it was he who first suggested our present system, the advantages of which are incalculably greater than those first constructed by Napier, at the same time that he laboured more than any one in the construction of them. In the present state of analysis, many comparatively short methods may be employed for this purpose, that were unknown to the early writers, and for want of which the labour attending the first computation was exceedingly great, notwithstanding they had certain means of abridging the operation in particular cases; a minute and interesting account of which, with an explanation of their several modifications, is given by Dr. Hutton in the introduction to his Mathematical Tables, to which work the reader is referred for every information on this subject. The publications relating to logarithms are so numerous, that we can only find room to mention a small portion of them; but as it is useful to know which are reputed the best authors, and particularly the best editions of the same authors, we shall subjoin the following list, which may be considered as containing the most respectable and accurate works of this kind: The first Canon of Logarithms for natural Numbers, from 1 to 20000, and from 90000 to 101000, was constructed and published in 1624, by Briggs, with the approbation of the inventor, Lord Napier. Briggs' Logarithms, with their difference to 10 places of figures; as also the logarithmic sines, tangents, &c. by George Miller, London, 1631. Sherwin's Mathematical Tables, published in 8vo. London, 1704, form the most complete collection of any we have yet noticed; containing, besides the logarithms of all numbers from 1 to 101000, the sines, tangents, secants, &c. versed sines, both natural and logarithmic, to every minute of the quadrant. The first edition was printed in 1706, but the third, published in 1742, as revised by Gardiner, is considered as superior to any other. The fifth and last edition, published in 1717, is so incorrect that no dependence can be placed upon it. Dr. Hutton's Mathematical Tables contain the common hyperbolic and logistic logarithms; also sines, tangents, secants, and versed sines, both natural and logarithmic; together with several other tables useful in mathematical calculations; to which is prefixed, a history of the discoveries and writings of the most celebrated authors on this subject. This work was first published in 1785, since which time it has passed through five editions, and is much esteemed for its accuracy. Taylor's Tables of Logarithmic Sines and Tangents, to every second of the quadrant; to which is prefixed, a Table of Logarithms from 1 to 100000, is a very valuable work, and has a useful introduction, composed by the late astronomer royal, Dr. Maskelyne.

LOGARITHMIC or **LOGISTIC SPIRAL**, is a curve having similar properties to the above, but differently constructed; thus, divide the quadrant of a circle into any number of equal parts in the points A, B, D, &c.; and from the radii CA, CB, CD, &c. cut off CA, CB, CD, &c. continually proportional, then the curve passing through the points A, b, d, &c. will be the logarithmic spiral. Hence the several areas are as the logarithms of the ordinates; and hence the denomination of the curve.

LOGIC, or the *Art of Reasoning*, is intended to guide and assist the intellectual powers of man in the investigation of truth, and in the communication of it to others. This science is not, therefore, a mere explanation of scholastic and barbarous phrases; nor a set of rules to teach the art of disputation; but it traces the progress of the human understanding in the acquisition of knowledge, and thus suggests the best methods of avoiding error, and discovering truth.

The operations of the mind in acquiring and communicating knowledge, are, "Perception," "Judgment," "Reasoning," and "Disposition;" and into these parts logic is divided.

Perception, or *conception*, is the attention which the mind gives to impressions made upon it, and the results of perception are sensations and ideas. Example. We can conceive of a horse, a tree; of motion, time, &c. which will produce corresponding sensations and ideas.

Judgment, is the operation of the mind by which we join two or more ideas together by an affirmation or negation. Sentences, called propositions, are the effect of judgment. Example. "This tree is high:" here are two ideas, viz. one of a tree, and another of its height: the sentence is complete and affirmative. "That house is not large:" this is a negative proposition. Both are the effect of judgment.

In *Reasoning*, we determine the relation between two ideas, by comparing them with a third idea, called the middle term. Example. If we affirm, that "God will make a difference between the evil and good," it is the result of reasoning, by which we suppose, that "A just being will make a difference between the good and evil;"—and that "God is a just being."

The result of reasoning is an inference; and the expression of an act of reasoning is called a syllogism. Example:

A Creator is to be worshipped.

God is a Creator;

Therefore, God is to be worshipped.

Here is a syllogism; and the inference is, that "God is to be worshipped."

Disposition is the proper arranging of our ideas upon any subject, so as to assist our own and others' conception and memory. The result of disposition is method.

Of Ideas. There are two modes of perception, viz. *sensation* and *reflection*. Sensation is the perception of an object by the organs of sense, which are *eye, ear, hearing, tasting, smelling, and touching*. By sight we acquire ideas of light and darkness, and colours; by hearing, of sounds, &c. Reflection is the perception, intellectually, of the operations of our minds, and by this we gain sensations and ideas.

Illustration: Reflection presupposes sensation, as its impressions are only the effect of the various powers of the understanding, employed about perceptions already in the mind.

A *Sensation* is the impression made upon the mind by an object actually present; an *idea* is a revived impression in the absence of the object. Illustration: The grand source and inlet of knowledge is sensation, which comprehends all the notices conveyed into the mind by impulses made upon the organs of sense.

Ideas are either simple or complex.

Simple Ideas are those that exist in the mind under one uniform appearance, without variety or composition, as a colour, or sound.

Complex Ideas are those that may be divided into two or more simple ideas, as a square, a triangle, &c.

Simple ideas enter the mind only by inlets appropriated to his purpose, and it cannot refuse to receive them.

Simple ideas are incapable of change; but they gradually wear out of the mind, unless revived by the same means by which they were originally acquired. Example: We soon forget the countenance of a man whom we have seen but once.

Simple ideas are capable of combinations to an indefinite variety of forms, and are the materials of all our knowledge.

Complex Ideas, or collections of objects, are produced by Composition, Abstraction, and Comparison. By Composition we add or augment, as, a waggon and horses. By Abstraction we select certain properties of an object, and overlook others, as when we contemplate a triangle, a square. And by Comparison, we have ideas of greater and less, &c.

Complex ideas are either representations of objects really existing, or collections made at the pleasure of the mind.

The objects really existing are either substances, or modes.

Substances are beings or things, subsisting by themselves; as steel, brass, &c. Modes are the properties of substances, and dependent upon them for support; as hardness, softness, brightness, extension, &c.

Our ideas of substances extend only to their properties.

Modes are either *essential* or *accidental*: an essential mode is that which is necessary to its existence, as solidity and roundness are essential to a bowl; an accidental mode is that which is not necessary to the existence of the subject, as roundness is only an accidental mode of a stone; the bowl cannot exist as a bowl without roundness, but a stone may.

Of Words. Words are articulate sounds used as the signs of ideas. The connexion between words and ideas is perfectly arbitrary; but, by frequent use, a term becomes so strongly associated with an idea, that it never fails to suggest it. The use of words is to record our own trains of ideas, and to communicate our thoughts to others: our ideas are recorded by being clothed in words, and communicated in writing. We communicate our thoughts to one another by a tacit agreement to annex the same ideas to the same words.

Language may be resolved into nouns and verbs, with their abbreviations.

Nouns express the names of things, and are either substantives, which are the things spoken of, or adjectives, which denote the qualities or circumstances belonging to them.

Verbs express modes of existence, either simply, as "to be;" or existence in an active state, as "to run," "to walk," &c.; or existence in a passive state, as "to be elected."

Indecipherable particles are abbreviations of nouns and verbs, invented for the greater expedition of communicating our thoughts; thus *if* signifies *give*; and *signifies* *add*, being the imperatives of the verbs.

Simple words are the elements of language, as simple ideas are of all knowledge.

Of Definition. Definition is an enumeration of the chief simple ideas of which a compound idea consists, in order to ascertain or explain its nature and character.

Definitions are either nominal, of the name, or real, of the thing.

A *nominal* definition is an enumeration of certain marks or characters, sufficient to distinguish the thing defined from any other. Such is the definition of a square, as a figure containing four equal sides, and four right angles.

A *definition* of a thing includes an enumeration of the principal attributes of the thing, in order to explain its nature; thus an isosceles triangle is a figure having the angles at the base equal.

Definitions are either *accurate* or *inaccurate*; the first are strictly definitions, the second only descriptions.

The rules for a good definition are, 1. It should be clear, and more obvious than the thing defined. 2. It should agree to all the species included under the same idea. It must be peculiar to the thing defined. 4. It should be short. 5. Neither the thing defined, nor a mere synonymous name, should make any part of the definition.

Judgment. When two ideas are compared, they either concur, as, snow and whiteness, or coincide, as God and Creator; they do not concur, as vice and usefulness; or they do not coincide, as man and eagle. This concurrence and coincidence of ideas, or the want of it, we call judgment, which is, in fact a third or intervening idea.

The sources of judgment are consciousness, sense, intuition, and testimony.

Consciousness is the mind's perception of its own existence, faculties, and operations. The senses teach us the existence, properties, and powers of external objects; and the foundations of natural knowledge.

Intuition is the instant perception of the relation between two ideas, as "the whole is greater than any of its parts, and equal to all its parts."

Testimony is the criterion of facts, which do not fall immediately under our own observation. Illustration: The province of testimony is the proof of facts, which having happened in past times, or in distant places, have not fallen under the cognizance of the senses. Testimony must be true when the relater is not himself deceived, and does not intend to impose on others.

A judgment or mental proposition, is that union or separation of the ideas which is the result of the act of judging, and it may exist without any connexion with words.

A proposition is a judgment clothed in words, and it consists of three parts, the subject, the predicate, and copula. Example 1. Virtue is excellent. 2. Gold and silver are the most precious metals. Here *virtue* in the one example, and *gold and silver* in the other, are subjects; the verbs *is* and *are* are the copula; *excellent* and *most precious metals* the predicates.

The *subject* of a proposition is the idea concerning which something is affirmed or denied; the *predicate* is the idea united to, or separated from the subject; the *copula* is the sign which represents the union or the separation of the subject of the predicate. Illustration: In the proposition, "Wisdom is the principal thing." *Wisdom* is the subject, *is* the copula, and *principal thing* the predicate.

The several parts of a proposition are not always distinctly expressed, but are always understood; thus, "I walk," "he pleads," may be resolved into "I am walking," "he is pleading."

Propositions may be divided into affirmative and negative; the *affirmative* connects the predicate with the subject, as "gold is heavy;" the *negative* separates the predicate from the subject, as "Man is not perfect." Propositions are universal and particular; in an *universal* proposition, the predicate extends to the whole subject, as "All men are mortal." "No man is truly happy." The signs of an universal proposition are usually the words *all*, *every*, *no*, *none*. In a *particular* proposition, the predicate is limited to a part of the subject, as "Some people are good." "Many philosophers have been deceived."

The signs of particular propositions are, *some*, *many*, *few*, &c.

Propositions are true or false: a *true* proposition unites ideas that agree, and separates those that disagree, as "God is good." "Men are not truly wise." A *false* proposition affirms an agreement between ideas that disagree, and a disagreement between those which agree, as "A good king oppresses his subjects." "Virtue is not the road to solid happiness."

A demonstrable proposition is one that may be proved by a train of reasoning, called demonstration, as "Any two angles of a triangle, taken together, are greater than the third." Illustration: Demonstration is a succession of connected propositions, beginning with self-evident, and advancing to remoter truths: such is the mathematical demonstration, which begins with definitions: from these it advances to axioms, or self-evident propositions; and thence to more remote truths.

Corollaries are inferences deduced from truths already demonstrated.

Of Reasoning. Reasoning determines the relation between

two or more ideas, by the intervention of another, or third idea. Illustration: If I wish to compare two right lined figures, as ABC DE, and ABC DEF, (see fig. 1

and 2,) with regard to magnitude, I find the thing impossible, on account of their disagreeing forms, one having six sides, and the other only five. I must therefore look for a third idea, in this case, a third figure, with which I may compare both the given figures. All right-lined figures may be divided into triangles, and the areas of all triangles are equal to the base multiplied into half the perpendicular height. Hence I easily compare the two given figures, in respect to magnitude, by the intervention of the third idea, a triangle. See the articles GEOMETRY and MENSURATION.

If the two given ideas agree with the third idea, it is evident that they must agree with each other. If one agrees, and the other disagrees, their mutual disagreement is inferred.

Every act of reasoning consists of three judgments, in two of which the given ideas are compared with the third idea, and in the last they are joined to or separated from each other. Illustration: In the figures above mentioned, the first two judgments are employed in considering into how many triangles each figure may be divided; and in the last judgment, we compare them together with respect to magnitude.

A syllogism is the expression of an act of reasoning, and includes three distinct propositions. The intermediate idea made use of, (as that of a triangle just noticed,) to discover the agreement or disagreement we are in search of, is called the middle term, and the two ideas with which this third is compared, are called extremes.

Example 1. Suppose a comparison to be made between industry and honour, and utility be the third idea, then the syllogism will stand,

Whatever is useful is honourable.

Industry is useful;

Therefore industry is honourable.

Example 2. If the inquiry be, whether a man is bound to cultivate his mind, I say,

Every creature possessed of reason is bound to cultivate his mind.

Man is possessed of reason;

Therefore man is bound to cultivate his mind.

In syllogisms the proposition containing the inference is called the *conclusion*; the two preceding positions are the *premises*. Of the two premises, that is called the *major proposition* in which the greater extreme is compared with the middle term; the *minor proposition* is that in which the less extreme is compared with it.

Example. In the syllogism,

Truth is venerable.

Christianity is truth;

Therefore Christianity is venerable.

"Christianity," "Venerable," and "Truth," are the three terms of the syllogism. "Christianity" and "Venerable" are the extremes, and "Truth" is the middle term. "Venerable" is the *major*, and "Christianity" the *minor term*. "Truth is venerable," "Christianity is truth," are the *premises*; "therefore Christianity is venerable," is the *conclusion*. "Truth is venerable," is the *major proposition*; "Christianity is truth," is the *minor proposition*.

[Syllogisms may be almost indefinitely varied, and each variety has obtained a distinct name: in this place a very few will be noticed.]

Hypothetical syllogisms are those in which the major premise is an hypothetical proposition.

Exam. If there be a God, he ought to be worshipped.

But there is a God;

Therefore he ought to be worshipped.

A *dilemma* is a syllogism in which the consequent of the major is a disjunctive proposition, which is taken away in the minor: or it is an argument by which we endeavour to prove the absurdity or falsehood of some assertion.

Exam. If God did not create the world perfect in its kind, it must have been from want of inclination or power.

But it could not have been from want of inclination, or want of power.

Therefore he created the world perfect in its kind.

* See "A Compendium of Logic, by the Rev. Thomas Belsham, as introductory to his Elements of the Philosophy of the Human Mind," &c.

Analogy is an argument from proportionable causes to proportionable effects; and from similarity of circumstances to similarity of consequences.

Ex. All matter with which we are acquainted gravitates;

Therefore gravitation is an universal property of matter.

Illustration: By this mode of argument, we infer that the sun will rise to-morrow, and the next day, and so on. Thus the philosopher believes that the planets are inhabited: and the man of business regards it as certain that a dishonest and avaricious man will take an undue advantage in trade, where the opportunity occurs, as that fire will burn, or a ball will roll down a hill. In other cases the argument cannot be much depended on, as when we intend to draw conclusions concerning the conduct of voluntary agents; this is owing to the difficulty which one person has to enter into the views, objects, and feelings of another, and consequently to foresee in given circumstances, how another man will act.

LOGWOOD. The tree which yields it is called by Linnaeus, *hematoxylum campechianum*. Logwood is so heavy as to sink in water, hard, compact, of a fine grain, capable of being polished, and scarcely susceptible of decay. Its predominant colour is red, tinged with orange, yellow, and black. It yields its colour both to spirituous and watery menstrua.

LOLIUM PERENNE, Ray or Rye-grass. This has been long in cultivation, and is usually sown with clover under a crop of spring corn. It forms in the succeeding autumn a good stock of herbage, and the summer following it is commonly mown for hay, or the seed saved for market, after which the land is usually ploughed and fallowed, to clear it of weeds, or as a preparation for wheat, by sowing a crop of winter tares or turnips. The seed is about six or eight pecks per acre, and ten pounds of clover mixed, as the land best suits. Although this is a very advantageous culture for such purposes, and when the land is not to remain in constant pasture; yet it is by no means a fit grass for permanent meadow, as it exhausts the soil, and presently goes into a state of decay for want of nourishment, when other plants natural to the soil are apt to overpower it. There are several varieties of this grass: some with the flowers double, others with branched panicles; some that grow very luxuriantly, and others that are little better than annuals; and there is also a variety in cultivation called Pacey's rye-grass, much sought for. But a fine rich soil only will produce a good crop, and the principal difference, after all, is owing more to cultivation or change of soil, than to any real difference in the plant itself.

LONG, ROGER, an English astronomical professor, was born in 1679, and received his college education at Cambridge; he became master of Pembroke Hall, and Lowndes's professor of astronomy. He is chiefly known as an author, by a treatise on astronomy, in two volumes; the first of which was published in 1742, and the second in 1764.

LONGIMETRY, the measuring of lengths or distances, both accessible and inaccessible. Accessible distances are measured by the application of some measure a certain number of times, as a foot, chain, &c. And inaccessible distances are measured by taking angles, &c. by means of proper instruments, as the *circumferenter*, *quadrant*, *theodolite*, &c. This embraces a great number of cases, according to the situation of the object and observer, a variety of which are given in various parts of this Dictionary.

LONGITUDE, in Astronomy, is the angular distance of any star or celestial body from the vernal equinoctial point, that is, if a great circle pass through a star perpendicular to the ecliptic, the arc of the ecliptic intercepted between the intersection of it with this circle, and the vernal equinoctial point, will be the longitude of the star.

Longitude, in Geography and Navigation, is the measure of the angle included between the meridian of any place, the longitude of which is required, and a certain fixed meridian from which the longitude is reckoned; or it is the number of degrees, minutes, &c. intercepted between a certain fixed point of the equator, and the intersection of the meridian of the place with the same circle. This we have illustrated; see **LATITUDE**.

Degrees of Longitude vary with the parallels of latitude, being every where as the cosine of the latitude. The following

61.

Table shows the length of a degree of longitude, corresponding to every degree of latitude from the equator to the pole, as expressed in English and geographical miles.

TABLE.

Deg. of Lat.	Deg. Lon. Geogr. Miles.	Deg. Lon. English Miles.	Deg. of Lat.	Deg. Lon. Geogr. Miles.	Deg. Lon. English Miles.	Deg. of Lat.	Deg. Lon. Geogr. Miles.	Deg. Lon. English Miles.

LONGITUDE Stars, is a term used to denote those fixed stars which have been selected for the purpose of finding the longitude by lunar observations; as, a *Arietes*, a small star without the zodiac, about 22° to the right of the Pleiades. *Aldebaran*, in the Bull's-eye, a large star, about half way between the Pleiades and the star which forms the western shoulder of Orion. *a Pegasi*, a star about 44° to the right of a *Arietes*, nearly in a line with this latter star and the Pleiades. *Pollux*, to the northward of Aldebaran, one of the two bright stars in the constellation Gemini. *Regulus*, about 38° SE of Pollux, the southernmost of four bright stars to the N. E. of Aldebaran. *Spica Virginis*, a white sparkling star, about 54° S. E. of Regulus. *Antares*, lying to the right hand of Regulus, and about 45° from Spica Virginis. *Formahault*, lying about 45° to the south of a *Pegasi*. *a Aquila*, a star about 47° to the westward of a *Pegasi*.

LONGITUDE by Time Keeper, is estimated by the difference between the time at the place, and the time indicated by one of those improved watches, called time keepers.

LOOF, the after part of a ship's bow, or that where the planks begin to be incurvated as they approach the stem. Hence the guns which lie here are called *Loof Pieces*.

LOOK-OUT, a watchful attention to some important object or event, which is expected to arise from the present situation of a ship; there is always a look-out kept on a ship's fore-castle at sea, to watch for any dangerous object lying near her track, or for any strange sail heaving in sight, &c. The officer of the watch accordingly calls frequently from the quarter deck, to the person appointed for this service, "look out afore there."

LOOMING, an indistinct appearance of any distant object, as the sea-coast, ships, mountains: "that ship looms large," "the land looms high, &c.

LOOMS, Power. The number of power looms in the manufacturing district which surrounds Manchester has been, after careful inquiry, stated to be 30,000.

The quantity of cotton converted into yarn in Great Britain and Ireland in one year is about..... 160,000,000 lbs.
The loss in spinning may be estimated at 1½ on per lb..... 15,000,000 lbs.
Quantity of yarn produced..... 145,000,000 lbs.

Amount, supposing 1s. 8d. to be the average price per lb..... £ 10,875,000.

If every person employed in spinning produces 900 lb. per annum, the number of persons employed is 161,111. The number of spindles employed, supposing each to produce 15 lb. weight per annum, is 9,666,666. The capital invested in buildings and machinery cannot be less than £10,000,000. It is calculated that the rental of Manchester, including Salford, Chorlton, Rew, &c. which form part of the same town, will be increased at least £15,000 this year (1825) by new buildings. The increase is chiefly in cottage property, under £12 a year rent.

Goodman's Improved Silk Loom.—The improvements of this machine apply to that description of loom that usually weave narrow articles, as tapes and ribbons, (commonly called Dutch engine looms,) and consist principally in a novel arrangement of the shuttles and slays in the battens. The general appearance of the loom, with its improvements, is shewn in the plate, fig. 1. which is an end view of the machine, exhibiting the disposition of the warps for two sets of shuttles. Fig. 2. shews a part of the front of the batten; and fig. 3. the back of the same; by which the situation of the shuttles, and manner of fixing the slays will be seen, and also the construction of the driver. The front of the batten, fig. 2, is formed by three planks, one of which is fixed to the top-rail by a series of slay screws: the bottom plank is secured to the lower rail in a similar manner; and the middle plank is fastened to the slay rail by a series of screws or pins, as seen in the back view, fig. 3. These screws must have shoulders to leave an open space between the back of the plank and the slay rail, for the action of the drivers.

The shuttles made in the ordinary construction, are introduced in the races between the planks, and the horizontal action of the drivers impels them to and fro through the warp, in the usual manner. The driver in the ordinary engine loom is formed like a ladder, but in this improved loom it is made with teeth extending from the top and bottom rails of its frame, shewn by dots; and these teeth may, if it should be thought desirable, be united together for the purpose of giving them stability, by diagonal pieces crossing the middle of the batten.

For the general operation of the loom, see the Plate of Looms: *bb*, fig. 1, are the rollers, upon which the material is wound, to form two warps; from thence the threads proceed (as shewn by arrows in the figure) in the usual way, up and down over the weighted pulleys, to the back slays *b*, then under the warp-rollers *c* to the leashes *d*, which are looped to arrange with each set of warps, and through which each distinct warp passes to its respective slay. The raising and depressing of the treadles *e*, worked by the feet of the weaver, cause the leashes alternately to move up or down, by which the warp threads are opened; the batten *f* is then pushed back, and the shuttles passed through the open space between the threads. The shifting of the treadles and leashes now cause the intervention of the threads to be made fast, which are beaten up firm, by bringing the batten *f* forward. The continued action of the loom in this manner, and the passing of the shuttles to and fro, produces that intervention of the warp and weft which is the ordinary operation of weaving.

The work thus woven, is drawn off through small apertures in the breast piece *g*, and thence proceeds to the work roller *h*, over which it passes up the back castle *i*, where it is distended by the weighted bags and pulleys; from thence it is carried over the top castle *k*, and through holes in the work castle *l*, where it is made fast by wedges, to prevent it from running back, and as the length of the work accumulates, it is wound round the bobbins *m*.

Although we have described the whole construction and operation of this improved engine loom, the invention claimed by the patentee consists merely "in the new arrangement of the shuttles and the slays, as connected with the batten and the knitting of the leashes, to arrange with the same in the manner above described.

Description of an improved Loom, by which Purses, Pockets, Sacks, &c. may be woven without requiring a Side-seam, and Work in general may be better executed.—In this loom, represented by fig. 10, (see Plate of Looms,) an oblong frame, *A*, is laid down horizontally, and secured at the four corners with triangular braces, to keep the frame properly square. Three of these braces, *BBB*, are visible. Four posts, *CCCC*, are fixed upright in mortise holes on the above frame. The front posts are supported, both behind and before, with diagonal timbers, *DDDD*, to keep the breast-roll *E* from giving way in the least by the heavy stroke of the batten *FF*, on the quarter or work. The two hinder posts, *GG*, are held firm by two diagonal supports, *HH*, within the loom, to bear against the counter-weights *II*, and the great weight *V*, hanging on the work *K*, and the force of the batten *F*.

A loom constructed upon this plan, without shorings or supports, will make both strong and slight works firm and good, and its advantages are therefore more important than might be supposed. As journeymen weavers generally live in low-rented houses, the floors and party-walls of the rooms where they weave, are mostly bad and weak; so that the common looms cannot be firmly placed, and the man finds great difficulty in getting his loom into tolerable order; yet if the loom is not set square, and prevented from giving way while used, no work can be made strong and good. The silk chafes and cuts, and the workman is harassed for want of knowing the real cause of the mischief, or not having skill to correct it. These inconveniences are obviated by the bottom frame braced as above mentioned; any ordinary workman can set up this loom well, though it requires a person of considerable judgment to set up an ordinary one. It is a common fault, where shorings or supports are used, to make them too long and slender, in which case, even when they rest against good walls, there is a trembling motion, and if the shake only amount to the hundredth part of an inch, it will take out that stiffness which ought to be in the work. In consequence of the defects thus occasioned in the manufacture, the poor weaver is often turned out of employment, and the master suffers in his property, as he cannot sell the fabric at the price it ought to be worth. A variety of other disadvantages, well known to the trade, attend the use of the loom, not properly squared, shored, and fixed; but it may suffice to refer to one, which is material. A loom set up with stays, must remain always at the same place, although the light may frequently not be suitable to the work, and even when the moving of the machine a few inches would render the light proper. In this point of view, the improved loom is particularly convenient.

Method of Weaving Sacks, &c. in the Loom above described.—*L*, the seat of the loom. *M*, the treadles, six in number, to raise the harness. *N*, the counter-meshes to raise the tumblers *O*, moveable on a pin a little beyond their centre, and which act on the harness *P*, by raising such parts thereof as they are attached to at their extremities. *Q*, the work in the loom. *R*, the reed which strikes the shoot or weft close up. *S*, the back beam on which the warp or thread is wound. *TT*, the rods to preserve the crossings of the threads. *V*, the main weight suspended by a lever *U*, from a bar *W* near its centre; the other end of the lever is fastened by a cord to the bottom frame of the loom at *X*. *Y*, the rack on the working beam. *Z*, the catch, to hold the teeth of the rack.

To weave a sack, press down the second treadle on the right hand side, and throw one shoot with the shuttle; next press down the second treadle on the left hand side, and throw another shoot; then proceed in the same manner with the third on the right, and the third on the left, till a sufficient quantity is made; then work the two outside treadles and two shoots. In weaving sacks, it is necessary, between the finishing of one sack and the commencement of another, to pass a thin slip of wood through the threads, in order to form a space between the two sacks.

Loom for making Fishing Nets

A Loom for Weaving Fishing-nets.—A machine for weaving fishing-nets has long been a desideratum; fishermen frequently having their nets broken by dog-fish, and other marine animals, and they experience many difficulties after such accidents, on account of the length of time required by the present mode of netting, in repairing their injured nets, or in making others. A fisherman is sometimes compelled, from these obstructions, to relinquish fishing for a whole season. Any method, therefore, which leads to accelerate the fabrication of nets, without increasing the expense of them, must be beneficial to the community. These considerations awayed the inventor of the loom described below, in devoting much of his attention to this branch of manufacture, until he succeeded in uniting economy and expedition. The loom is represented by figs. 1 to 9, in the Plate.

Fig. 1, is the machine in a state ready to begin working, supported in a wooden frame. A is a beam on which the twines for the net are rolled, in number equal to the knots tied, and from which they pass through circular tubes fixed in a bar B, (shewn by dotted lines through the pulley, but seen better in fig. 2,) which is fixed near the circumference of two equal pulleys, C C, that turn on their axes by means of a cross treadle, with small pulleys at each end, D D, through which passes a band, one end of which is fastened on the frame at E, and the other on the pulley C. At F, the band through the other pulley has one end fastened on the frame at G, and being wound round the farthest pulley C, is fastened on the under side of it, which, by the alternate action of the treadle on its axis H, moves the pulleys C C, and circular tubes, from their situation in fig. 1 to that in fig. 3, and back again.

In the centre of the pulleys C C, is fixed another bar P with a dove-tail groove, where the pins that contain the twine are supported, (it being necessary to have two threads for every mesh, also one pin more than there are tubes.) In a groove under the dove-tail is a slider L, moved by a wire K, fixed in each end of it, having pins in it, by which it moves the pins backwards or forwards over the notches in the bar I, so as to cast a part of the knot: the pulleys C C, and bar B, move round the bar I as an axis, but independent of it; the bar I being fastened through the pulleys to the frame.

M is a moveable bar (centred within two supporters, N N, having two joints) with hooks, both for catching the twine at the end of the circular tubes, and by crossing the hooks to the other side of the points of the tubes, to give the twine a turn for forming the knot; and by raising the points of the hooks, the ends of the tubes enter between them, as shewn in fig. 4, and by the circular motion of the bar B, when the two pulleys C C are turning on its centre by the foot, on the end, No. 1, of the cross treadle; and until the knots are formed are close to the bar B, fig. 3, (it is then what is called a running knot,) a part of which falls into a notch cut below the level of the supporters of the pins in the bar I; the pins must then be slid over the notches that contain the twine, the knot is then cast, and then by the foot on the other end, No. 2, of the cross treadle, the points of the tubes are returned to their former position; remove the knot by disengaging the hooks and the tubes, the knots are then made tight as the wrought part of the net is rolled on the beam O, on one end of which there is a pulley, P, with a band that communicates with the pulley on the end of a short roller Q, in which are fixed four cross bits of wood, that answer the purpose of treadles for the feet, by which it is drawn tight.

R is another short roller, communicating with the roller A, serving to give out the proper quantity of twine for the length of the meshes, or to hold it while the other roller tightens the knot. S is the seat.

Fig. 2, is a plan of the machine; the moveable bar and treadles are left out to prevent confusion.

Fig. 3, is the situation of the running knot when the pins pass through it.

Fig. 5, is the tube in the same position, shewing the manner in which the knot is twisted round it; and having the pin and slider L taken out of the bar I, the dotted lines shewing at what height they come together. In the slider L there are two pins, T T, to prevent its rising high enough to touch the string;

and in the bar I there are two wires O O, like staples, to support the slider L in its place.

Fig. 6, is the moveable bar M with the hooks.

Fig. 7, shews the hooks at large.

Fig. 8, is the bar I, shewing the notches in which the strings lie to let the pins pass over them, (when the tubes are brought over as in fig. 3.)

Fig. 9, is the slider L, with the pins that move the pins.

It appears, by a statement of the inventor, that the nets used in the northern fisheries are of one breadth throughout. He estimates that he can make three courses of one hundred meshes each, in one minute; that such a loom should be about 3½ feet wide, and would cost about fifteen or sixteen pounds.

A Loom to be worked by Steam or Water.—A loom having been invented, which may be wrought by steam, water, or any other first mover of machinery, and its practical value having been ascertained by an extensive trial, it will be interesting and useful in this publication, to shew what has been accomplished in this branch of ingenuity, by a record of its properties. A plate of any ordinary size would not be adapted to shew with clearness the principles and construction of this curious machine; but a working model is in the possession of the Society for the Encouragement of Arts, &c. and looms upon this plan possess the following advantages:—1. From 300 to 400 of them may be worked by one water-wheel, or steam-engine, all of which will weave cloth, superior to what is done in the common way. 2. They will go at the rate of 60 shoots in a minute, or two yards of a nine-hundred web in an hour. 3. They will keep regular time in working, stop, and begin again, as quickly as a stop watch. 4. They will keep constantly going, except at the time of shifting two shuttles, when the web on the pins is done. 5. In general, no knots need to be tied, and never more than one, in place of two, which are requisite in the common way, where a thread breaks. 6. In case the shuttle stops in the shed, the lay will not come forward, and the loom will instantly stop working. 7. They will weave proportionally slower, or quicker, according to the breadth and quality of the web, which may be the broadest now made. 8. They may be mounted on a harness, or spot headles, to weave any pattern, twilled, striped, &c. 9. There is but one close shed, the same in both breadths, and the strain of the working has no effect on the yarn behind the rolls. 10. The bore and temples always keep the same proper distance. 11. There is no time lost in looming, or cutting out the cloth; but it is done while the loom is working, after the first time. 12. The web is well stretched, and exactly even to the fabric required. 13. Every piece of cloth is measured to a straw's breadth, and marked where to be cut, at any given length. 14. The loom will work backwards, in case of any accident, or of one or more shoots missing. 15. Every thread is as regular on the yarn beam as in the cloth, having no more than two threads in the runner. 16. If a thread should appear too coarse or fine in the web, it can be changed, or any stripe altered at pleasure. 17. They will weave the finest yarn more tenderly, and regularly, than any weaver can do with his hands and feet. 18. When a thread either of warp or weft breaks in it, the loom will instantly stop, without stopping any other loom, and will give warning by the ringing of a bell. 19. A loom of this kind occupies only the same space as a common loom; the expenses of it will be about half more; but this additional expense is more than compensated by the various additional machinery employed for preparing the yarn for the common loom, and which this loom renders entirely unnecessary. 20. The reeling, winding, warping, beaming, looming, combing, dressing, fanning, greasing, drawing bores, shifting headles, rods, and temples, which is nearly one-half of the weaver's work, together with the general waste accompanying them, which is about six per cent. of the value of the yarn; and all which occur in the operations of the common loom, do not happen with this loom, which, by its single motion, without further trouble, performs every operation after the spinning, till the making of the cloth be accomplished; by which, independently of the saving of the waste, the expense incurred for reeling, warping, winding, &c. is saved, amounting to above twenty per cent. of the yarn. 21. The headles, reed, and brushes, will wear longer than usual, from the regularity of their motion. 22. More than

one-half of the workmanship will be saved; one weaver and a boy being quite sufficient to manage five looms of coarse work, and three or four in fine work.—The first attempt of the inventor of the above loom, towards constructing such a machine, was made in the year 1789; at which time he entered a caveat for a patent, but relinquished the idea of obtaining one, and afterwards made many improvements upon the original plan. In 1796, a report in its favour was made by the Chamber of Commerce and Manufactures at Glasgow; and in 1798, a loom was actually set at work, in J. Monteith's spinning works, at Pollockshaws, four miles from Glasgow, which answered so well that a building was erected by J. Monteith to hold thirty of the looms, and afterwards another to hold two hundred.

Among the most ingenious inventions, or rather improvements in this useful machine, is the

Patent Power Loom, invented by Archibald Buchanan, Esq. of Catrine Cotton-works, one of the partners of the house of James Findlay and Company, whereby a greater quantity of cloth may be woven in a given time without injury to the fabric, than by any application of power for that purpose heretofore employed. This invention consists in the application of two eccentric wheels, A and B, represented in fig. 12, (see the Plate,) to a weaving-loom, impelled by machinery, as represented in figs. 11 and 12; and the application of these wheels to the said loom is particularly exhibited by fig. 12, as explained by the description hereinafter set forth. The inventor claims no part of the said loom, or of its construction, as his invention, or as forming any part of his right of patent, except the application thereto of the said two eccentric wheels.

A reference to the drawings in fig. 11 and 12, and the description hereunto annexed, will enable any person of ordinary mechanical skill, to understand and execute the application and operation of the said two eccentric wheels, either to this loom, or, by slight alterations which will be obviously suggested, to the ordinary weaving looms at present in use by the public. The lay *g*, attached to the rod *k*, vibrating upon its centres below, is connected with the eccentric wheel, B, by means of the crank-rods, at F. This wheel or pinion, B, receives its motions from the wheel A, and the method by which these wheels are constructed, and the manner in which they are applied, are now to be particularly described.

Both wheels, as already mentioned, and as will at once appear by inspecting the drawings, and, more particularly, fig. 12, are what is usually termed *eccentric*—that is to say, their circumferences, in which the teeth are cut, deviate from the common circular form, in such a ratio as may be required, in order to give the desired motion to the lay. In order to construct such a wheel A, in weaving plain cloth, and which is fixed upon the treadle-shaft, *q*, in fig. 11 and 12, the following descriptions and explanations, if carefully attended to, will be sufficient. Its greatest diameter being about 19 inches, and its smallest diameter about 16 inches—its deviation from the circular form amounts to about three inches. This deviation, however, may be increased or diminished, at the discretion of the constructor, and according to the variation of velocity which he wishes to communicate to the reciprocating motion of the lay. To obtain the proper curve of eccentricity, let two eccentric circles be drawn, corresponding with the greatest and smallest diameters. Divide these circles into any convenient number of equal parts; as, for example, 64, and draw radii from the centre to the points of division in the external circle. Divide the space between the circles into the same number of equal parts with the circumference, one of which being set off upon the first radius, two upon the second, and so on progressively, until the whole are set off, points will be obtained, through which a curved line being drawn, the required form of the circumference will be marked off upon each quadrant of the wheel. The highest points, as will appear by the drawings, are at the two extremities of a diameter line, bisecting the external circle and the lowest points, at the extremities of another diameter line, bisecting the internal circles at right angles to the former. Thus, the form obtained bears some resemblance to an ellipse, with its conjugate and transverse diameters. The pinion B must of course be constructed so as to correspond with, and work into, the wheel A. To effect this, it is merely necessary to draw circles as in the former case, corresponding with the greatest and the

smallest diameters required. Then set off one-half of the radii drawn upon the wheel A, the pinion being half its diameter, and add, progressively, to each radius of the pinion, as many equal parts as were taken from each corresponding radius of the wheel, and *vice-versa*. The semidiameter of the pinion will thus correspond, in every point with each quadrant of the wheel, and the pinion will revolve twice whilst the wheel performs one revolution, as before stated—thus communicating two accelerated strokes to the lay, for each revolution of the treadle-shaft moving the wheel A. The circumferential forms of both being thus obtained, the teeth are to be cut and rounded off so as to work properly into each other in revolving upon their respective axes. Though the wheel A will thus produce two revolutions of the pinion B, other proportions may be adopted when deemed expedient, and as may suit the motions to be communicated to a greater number of treddles for weaving plain, tweeled, or figured cloths. Those conversant with the art of weaving, will at once perceive, that a varied speed applied to the reciprocating motion of the lay, is of the greatest advantage, and such as will keep the lay as nearly stationary as convenient at the point where the shuttle is thrown across the web; and when the shed, or divided portions of warp, are sufficiently open to allow the shuttle to pass without injury to the warp threads. The lay, in returning, drives up the woof to the fell or verge of the cloth, with a smart stroke, whilst the shed or divided portions of warp are closing upon it, and when the least tension is given by the treadles to the warp threads. Mr. Buchanan ascertained, by experience, that in looms having such wheels, and the other apparatus before described, attached to them, the shuttle may be thrown across a web, 36 inches wide, 130 times per minute, without creating more breakage, in proportion to the quantity woven, than occurs in looms driven at the rate of 80 to 90 crossings of the shuttle per minute.*

Description of the Drawings.—The construction of the wheels A B, upon the application of which the patent is claimed, is delineated on the drawing, fig. 12.

Figs. 11 and 12 exhibit the two end views of the loom. In the following description, the same letters of the alphabet, and numerals, denote the same things in all the figures.

C D E F, denote the frame.—*a*, the strap communicating motion to the loom, at *b*; *b*, the fast and loose pulleys; *c*, a pinion fixed on the end of the pulley-spindle, and working into the wheel *d*, of triple the diameter, gives motion to the wiper-shaft, *q*. (See fig. 11.)—*k*, the lever and fork; and *l*, the spring for engaging and disengaging the loom at pleasure. (See fig. 11.) A lever is connected with the protecting pin of the lay, 2, for disengaging the loom, should the shuttle remain in the shed; *m*, a small eccentric wheel, fixed on the end of the wiper-shaft, *q*, (see fig. 11,) and connected with the lever *n*, (see fig. 11,) on the top of which is jointed a circular piece of iron, *o*, (see fig. 11,) which acts on the ratchet wheel *r*, and draws up the cloth as it is woven; and for varying the fabric in thickness, a ratchet-wheel of more or fewer teeth is applied; *p* is a catch bent in the same manner as *o*, which prevents the ratchet wheel, *r*, from returning back. By raising the handle *pp*, these catches are all disengaged. Behind the ratchet-wheel *r*, is fixed a small pinion working into the wheel, which is fixed on the end of the cloth-beam, *t*, (see fig. 11,) and covered with a card fillet for holding the cloth; *x*, is a small roll which receives the cloth from the beam *t*, and round which it is wound, by the motion of the beam *t*; *e*, the crank shaft which receives motion from the wiper-shaft, *q*, by the wheels A and B; *f*, the connecting-bar; *g*, the lay; *h*, the lay-sword. (See fig. 11 and 12.) S, the headle-roll bearer. (See fig. 11 and 12.) Q, the yarn roller bearer. (See fig. 11 and 12—11, the yarn-roll. (See fig. 11 and 12.) 14, a screw-box. (See fig. 11.); 1, is the protecting catch, for disengaging the loom when the shuttle stops in the shed; this catch is connected with a rod passing along the lay, on which the shuttle springs in the boxes act; when the shuttle fails to enter the box, this catch falls down, and, striking against the pin, 2, the lay is held fast, and the loom instantly disengaged by its connexion with the

* We understand that the patentee of this most important invention has himself driven the shuttle across the web 160 times per minute, without injury to the cloth; a speed which is nearly double of that of the looms at present in use.

lever which acts on the handle of the loom *b*. (See fig. 11 and 12.) 33, the heddle wipers, which, by acting on the friction pulleys fixed to the treadles, *b b*, alternately elevate and depress the treadles. (See fig. 12.) 77, the short marches connecting the heddles, 88 & 8, with the treadles, 66. (See fig. 12.) 44, friction pulleys, fixed to the heddle-wipers, 33, acting alternately on the treadles 55, to which the picking peg, *q*, for throwing the shuttle, is connected by bolts and screws; 10, is the warp-yarn beam. (See fig. 12.) A B, the eccentric wheels, for giving motion to the lay *g*. (See fig. 12.) *y*, the bearer of the boltfork, *k*, and which extends so as to connect another loom. (See fig. 11.) 14, the friction wheel; its appendages are two plates fastened to the beam-shaft, and upon one of them is glued a piece of leather, which is made perfectly flat by turning; the face of one of the appendage wheels is also turned flat, but this wheel is loose on the spindle; on the outside of it is the screw-box, 14, the outer part of which is made fast to the beam shaft, by a pin passed through it, the inner part of the box is then screwed up against the outer face of the said wheel, which presses the two surfaces together, and any degree of tension can be given to the warp-yarn by more or less screwing of the box, 14. (See fig. 11.) There is a small pinching screw-pin which is screwed into the outer box, the point of which enters a small cavity in the inner part of the box, and prevents it from unscrewing. 17, the long heddle marches connected to the heddles, 8, by cords, and to the short marches, 77, by wires. (See fig. 12.) *j*, the bearer of the pulley-shaft. (See fig. 11.)

Method of Weaving Cloth of extremely Fine Quality.—This improved mode of weaving consists in adding more thread of the warp within each dent or split of the reed than in the common way; for instance, where in the common mode there are only two threads in the reed, there are upon this plan three or four. The weft or shoot is thrown in the common way with a single thread. When the cloth is woven and taken out of the loom, it has the appearance of being barred or striped, the cause of the reed occasioning that part of the cloth struck with it to look thinner, owing to the threads of the warp being further apart. The cloth is then to be wet in water, and in that state to be repeatedly stretched across by the hands backwards and forwards corner-ways; by this means, the threads which apparently formed the stripe, or close part of the cloth, separate from each other, and become diffused at equal distances. The appearance of stripes being entirely removed, the cloth becomes of inconceivable fineness, and extremely regular in texture. This operation must, in cotton fabrics, be performed before the cloth goes to the bleach-ground. Silk goods, on being taken out of the loom, must be wet and well rubbed, as in the common mode of washing, and then stretched backwards and forwards, in the manner above directed for cotton goods. In silk goods the warp and weft may be both alike; in cotton goods the weft may be softer, but of the same fineness. Fine linen cambrics may be made on this plan, much superior to any hitherto made in France. Though there are three threads within each dent or split of the reed, whilst the cloth is weaving, yet the heddles or yealds lift up their threads alternately throughout the whole breadth of the cloth, and there are about 250 shoots in an inch. By this improvement, cotton, linen, and silk goods, can be made much sooner and finer, than by any method yet discovered. The inventor of it made a piece of plain silk cloth, from hand-thrown silk in the gum, that contained the amazing quantity of 65,536 meshes in one square inch. It is impossible to make a reed half so fine as to weave such cloth upon the present principles of weaving; and even if that could be done, no weaver could make use of it: but upon the above plan, which the inventor asserts he can teach in two minutes, as fine cloth may be woven in a twelve hundred reed, as by the old mode in a reed of twenty-four hundred, and with less rather than more trouble.

LOOP HOLES, certain small apertures formed in the bulkheads and other parts of a merchant ship, through which the small arms are fired on an enemy who boards her.

LOOPING, in Metallurgy, a word used by the miners of some counties of England, to express the running together of the matter of an ore into a mass, in the roasting or first burning, intended only to calcine it so far as to make it fit for powdering. This accident, which gives the miners some trouble,

is generally owing to the continuing of the fire too long in this process.

LOPEZ, or **INDIAN-ROOT**, in the *Materia Medica*.—The plant to which this article belongs is unknown. Neither the woody nor cortical part of the root has any remarkably sensible quality. A slight bitterness is perceptible; and it is recommended, like simarouba, in diarrhoeas, even of the colliquative kind, in half-drachm doses four times a day. Little of this root has been brought to Europe; but some of those who have had an opportunity of employing it, speak in very high terms of the effects obtained from it.

LOPHIUS, *Fishing Frog*, *Toad-fish*, or *Sea-devil*, a genus of the branchiostegous order of fishes.

LORANTHUS, a genus of plants belonging to the hexandria class, and in the natural method ranking under the 48th order, *Aggregatæ*.

LORD, a title of honour given to those who are noble either by birth or creation. In this sense, it amounts to much the same as peer of the realm, or lord of parliament. The title is by courtesy also given to all the sons of dukes and marquises, and to the eldest sons of earls: and it is also a title of honour bestowed on those who are honourable by their employments; as lord advocate, lord chamberlain, lord chancellor, &c.

LORD'S DAY. All persons, not having a reasonable excuse, shall resort to their parish church or chapel (or some congregation of religious worship allowed by the Toleration Act) on every Sunday, on pain of punishment by the censures of the church, and of forfeiting one shilling to the poor. The hundred are not answerable for robberies on the Lord's day. No person on that day shall serve or execute any writ, process, judgment, &c. except in cases of treason, felony, or breach of the peace, and the service thereof shall be void.

LORDS, **HOUSE OF**, one of the three estates of parliament, and composed of the lords spiritual and temporal.

LORDASIS, in the medical writings, a name given to a distempered state of the spine, in which it is bent inwards, or towards the anterior parts. It is used in opposition to gibbous, or hump-backed.

LOTION, in medicine and pharmacy, is such washing as concerns beautifying the skin, by clearing it of the deformities made by a preternatural secretion. Almost all the lotions advertised for sale as quack medicines, contain much deleterious matter, such as muriated mercury, and therefore ought never to be had recourse to.

LOTTERIES, games of hazard, in which small sums are advanced for the chance of obtaining a larger value. Lotteries are formed on various plans; but in general they consist of a certain number of tickets, which are drawn at the same time, with a corresponding number of blanks and prizes mixed together, and by which the fate of the tickets is determined. All lotteries, except those established by Act of Parliament, were, in the reign of queen Anne, declared to be public nuisances.

LOUGH, or **LOCH**, the former is the Irish, and the latter the Scotch term for lake. See that article.

LOVE, in a large sense of the word, denotes all those affections of the pleasing kind which objects and incidents raise in us; thus we are said to love not only intelligent agents of morally good dispositions, but also sensual pleasures, riches, and honours. But Love, in its usual and more appropriate signification, may be defined "that affection which, being compounded of animal desire, esteem, and benevolence, becomes the bond of attachment and union between individuals of the different sexes; and makes them feel in the society of each other a species of happiness which they experience no where else."

LOW-BELL, in Birding, a name given to a bell, by means of which they take birds in the night, in open champaign countries, and among stubble in October. The method is, to go out about nine o'clock at night in a still evening, when the air is mild, and the moon does not shine. The low-bell should be of a deep and hollow sound, and of such a size that a man may conveniently carry it in one hand. The person who carries it, is to make it toll all the way he goes, as nearly as may be, in that manner in which the bell on the neck of a sheep tolls as it goes on and feeds. There must be also a box made like a large lantern, about a foot square, and lined with tin,

but with one side open. Two or three great lights are to be set in this; and the box is to be fixed to the person's breast, with the open side forwards, so that the light may be cast forward to a great distance. It will spread as it goes out of the box; and will distinctly shew to the person that carries it, whatever there is in the large space of ground over which it extends, and consequently all the birds that roost upon the ground. Two persons must follow him who carries the box and bell, one on each side, so as not to be within the reach of the light to shew themselves. Each of these is to have a hand-net of about three or four feet square, fastened to a long stick or pole; and on whichever side any bird is seen at roost, the person who is nearest is to lay his net over it, and take it with as little noise as possible. When the net is over the bird, the person who laid it is not to be in a hurry to take the bird, but must stay till he who carries the light is got beyond it, that the motions may not be discovered. The blaze of the light and the noise of the bell terrify and amaze the birds in such a manner, that they remain still to be taken; but the people who are about the work, must keep the greatest quiet and stillness that may be. Some people are fond of going on this scheme alone. The person then fixes the light box to his breast, and carries the bell in one hand and the net in the other; the net in this case may be somewhat smaller, and the handle shorter. When more than one are out at a time, it is always proper to carry a gun, as it is no uncommon thing to spy a hare when on this expedition.

LOWERING, among distillers, a term used to express the debasing the strength of any spirituous liquor, by mixing water with it. The standard and marketable price of these liquors is fixed in regard to a certain strength in them called proof; this is that strength which makes them, when shaken in a phial or poured from on high into a glass, retain a froth or crown of bubbles for some time. In this state, spirits consist of about half pure or totally inflammable spirit, and half water; and if any foreign or home spirits are to be exposed to sale, and are found to have this proof wanting, scarce any body will buy it till it has been distilled again, and brought to that strength; and if it is above that strength, the proprietor usually adds water to it to bring it down to that standard. There is another kind of lowering among the retailers of spirituous liquors to the vulgar, by reducing it under the standard proof. Whoever has the art of doing this without destroying the bubble proof, which is easily done by means of some addition that gives a greater tenacity to the parts of the spirits, will deceive all that judge by this proof alone. In this case, the best way to judge of liquors is by the eye and tongue, and especially by that instrument called Hydrometer.

LOW WATER, the lowest point to which the tide ebbs. See the article **TIDE**.

LOXODROMIC CURVE, or **SPINAL**, the path of a ship when her course is directed constantly towards the same point of the compass, thereby cutting all the meridians at the same angle. See **RHUMB LINE**.

LOZENGE, in Heraldry, a four-cornered figure, resembling a pane of glass in old casements. See **HERALDRY**. Though all heralds agree, that single ladies are to place their arms on lozenges, yet they differ as to the origin of this privilege.

LOZENGE, is also a form of medicine, made into small bits, to be held or chewed in the mouth till they are melted there: the same with what are otherwise called trochisci "troches."

LOZENGES, among jewellers, are common to brilliant and rose diamonds. In brilliants, they are formed by the meeting of the skill and star facets on the bezel; in the latter, by the meeting of the facets in the horizontal ribs of the crown. See **FACTS**.

LUBBER, a contemptuous name given by sailors to those who know not the duty of a seaman.

LUBBER'S HOLE, is the vacant space between the head of a lower mast and the edge of the top; it is so termed from a supposition that a lubber not caring to trust himself up the futtock shrouds, will prefer that way of getting into the top.

LUCIDA, BRIGHT, an appellation used by way of distinction to several stars; as *Lucida Corona*, *Hydra*, *Lynx*, &c.

LUCIFER, a name given to the planet Venus, when she appears in the morning before sun-rise.

LUFF, the order of the helmsman to put the tiller towards the lee-side of the ship, in order to make the ship sail nearer the direction of the wind, hence

Luff Round, or **Luff a Lee**, is the extreme of this movement by which it is intended to throw the ship's head up in the wind.

Luff up, is to bid the steersman keep nearer to the wind.

Luff into a Harbour, is to sail into it close by the wind.

A ship is accordingly said to spring her luff when she yields to the effort of the helm by sailing nearer to the wind than she did before.

Luff Tackle, a name given to any large tackle that is not destined for a particular place, but may be variously employed as occasion requires. It is generally somewhat larger than the jingle-tackle, although smaller than those which serve to hoist the heavier materials into and out of the vessel, which latter are the main and fore tackles, the stay and quarter tackles, &c.

LUGGER, a vessel carrying three masts with a running bowsprit, upon which she sets lug-sails, and sometimes has top-sails adapted to them.

Lug Sail, a quadrilateral sail bent upon a yard which hangs obliquely to the mast at one-third of its length. These are more particularly used in the barca-longas, navigated by the Spaniards in the Mediterranean.

Lug Sail Boat, a boat carrying sails of the preceding description.

LUMBARGO, a fixed pain in the small of the back.

LUMBARIS, a name given to the arteries and veins which spread over the loins.

LUMBRICAL, a name given to four muscles of the fingers, and to as many of the toes.

LUMBRICUS, the *Worm*, a genus of animals belonging to the order of vermes intestina.

LUMINARIES, a term employed, by way of eminence, to denote the sun and moon.

LUMINOUS, or **PHOSPHORESCENT ANIMALS**, consist of insects and zoophytes, molluscous worms, &c. Insects furnish about twelve genera, all the species of which are luminous; among those we may notice the lampyris, or glow-worm, and fire-fly tribes; the fulgora, or lantern-fly; the scolopendra, or centipede; the fausus apocrocenus; the elater noctilucus, and the cancer fulgens. Among the worm-class, the principal are the pholas, or pholas, as it is now generally but erroneously denominated, the pyrosoma, the medusa phosphorea, the nereis nocticula, the pennatula, or sea-pen, and various species of the sepia or cuttle-fish. The atmosphere in some parts of Italy appears occasionally to be on fire, in the evening, from the great quantities of one species of the lampyris that throng together. A single individual of the South America fulgora, fixed upon the top of a cane, or other staff, will afford light enough to read by. The streams of light that issue from the elater noctilucus are so strong in the night, that even the smallest print may be read by their lustre. The acudia or fire-fly is of the beetle kind, and inhabits South America. The natives use them instead of candles, putting from one to three of them under a glass. Madame Meiran says, that at Surinam, the light of this fly is so great, that she saw sufficiently well to paint and finish one of them in her work on insects. The largest of the acudia are said to be four inches long, and to shine like a shooting star as they fly. They are thence called *Lantern-bearers*. The pyrosoma, when at rest, emits a pale blue lustre; but when in motion a much stronger light, variegated by all the colours of the rainbow. The pholas secretes a luminous juice, every drop of which illuminates, for a length of time, whatever substance it falls upon, or even touches; and the animal, after death, may be preserved so as to retain its luminous power for at least a twelvemonth. The noctilucous nereis often illuminates, by its numbers, the waters it inhabits, to a very considerable extent; and gives so bright a splendour to the waves, that, like the atmosphere when lighted up by the lampyris italica, they appear as though they were in a full flame. The organ from which the luminous matter is thrown forth, in these different animals, is of a very different character, and placed in very different parts of the body; sometimes in the head, sometimes in the tail, sometimes in the antennae, sometimes over the surface generally.

LUMPERS, labourers employed to load and unload a merchant ship when in harbour.

LUNAR, any thing relating to the moon; thus we say, *Lunar Cycle, Lunar Month, Lunar Year, &c.*

LUNAR Distance, in Navigation, a popular term used to indicate the following rule of finding the distance of the moon from the sun or some fixed star, for the purpose of ascertaining the longitude. Take the difference of the apparent altitudes of the moon and star, or moon and sun, and half the difference of their altitudes; also take half the sum and half the difference of the apparent distance and difference of the apparent altitudes; then to the log. sines of this half sum and half difference, add the log. cos. of the true altitudes (as corrected for semi-diameters, refraction, parallax, and difference, by means of the tables calculated for these purposes) and the complements of the log. cos. of the apparent altitudes, and take half the sum. From this half sum take the log. sines of half the difference of the true altitudes, and find the remainder among the log. tang., which being found, take out the corresponding log. cos. without taking out the arc, which is unnecessary. Lastly, subtract this log. cos. from the log. sine of half the difference of the true altitudes, increased by 10 in the index; and the remainder will be the log. sine of half the true difference.

Thus, for example, let there be proposed the following data, to find the true distances; *viz.*

Apparent dist.) and ☉	51°28' 35"
Apparent alt.) 's centre	12 30
Apparent alt. ☉'s centre	24 48
True alt.) 's centre	13 20 42
True alt. ☉'s centre	24 45 57
Apparent altitude of ☉	24 48
Apparent altitude of)	12 30

Different apparent altitudes 12 18

True altitude of ☉ 24 45 57
True altitude of) 13 20 42

2) 11 25 15

$\frac{1}{2}$ difference true altitude 5 12 37 $\frac{1}{2}$

Apparent distance 51 28 35
Different apparent altitude 12 18

2) 63 46 35

$\frac{1}{2}$ sum 31 53 17 $\frac{1}{2}$

2) 39 10 35

$\frac{1}{2}$ difference 19 35 17 $\frac{1}{2}$

Then by the foregoing rule we have the following computation:

Log. sine 31°53' 17 $\frac{1}{2}$	9.7228488
Log. sine 19 35 17 $\frac{1}{2}$	9.5253755
Co. log. cos. 12 30	0.0104185
Log. cos. 13 20 42	9.9881119
Co. log. cos. 24 48	0.0420206
Log. cos. 24 45 57	9.9580900

2) 39°24'08.743

19°02'34.371

Log. sine 5 42 37 8.9978159

Log. tan. of an arch 10.0256212

Corresponding log. cosine 9.3625337

Log. sine 25 34 54 $\frac{1}{2}$ 9.6352822

2

True distance 51 9 49

This is the direct method of determining the true distance, independently of any other tables than those of common logarithms, and what are found in the Nautical Almanack; but as this is the most laborious operation connected with the longitude problem, various other rules have been devised, which by the help of certain tables render the operation much more simple and expeditious; but in a work of this kind, we cannot properly enter upon the problem under that point of view, in consequence of our not having the necessary tables to refer to. The most approved of these rules may be seen by consulting Mackay on the Longitude.

LUNARE OS, in Anatomy, is the second bone in the first row of the carpus. It has its name from the Latin, *luna*, "the moon," because one of its sides is in form of a crescent.

LUNARIA, *Satin-flower*, or *Moonwort*, a genus of plants belonging to the tetradynamia class, and in the natural method ranking under the 39th order, Siliquosæ.

LUNATION, the time between one new moon and another; consisting of 29 days, 12 hours, 44 minutes, 3 $\frac{1}{2}$ seconds.

LUNE, **LUNULA**, in Geometry, is the space included between the arcs of two unequal circles, forming a sort of crescent or half moon; the area of which may in many cases be as accurately determined as that of any rectilinear figure. The lune was the first curvilinear space of which the quadrature was ascertained, and this is said to have been first effected by Hippocrates of Chios; and the figure still bears his name, being commonly denominated the lune of Hippocrates; the construction of which is as follows:

On the diameter of a semicircle describe a right-angled triangle, of which the angular point will necessarily fall in the circumference. Then on each of the sides AD, DB, describe a semicircle, and the two figures AGFD, DHEB will be lunes, and the area of them will be equal to the area of the right-angled triangle ADB.

LUNETTE, in Fortification, an enveloped counterguard, or elevation of the earth, made beyond the second ditch, opposite to the places of arms, differing from the ravelins only in their situation. Lunettes are usually made in ditches full of water, and serve to the same purpose as faussebrayes, to dispute the passage of the ditch. See FORTIFICATION.

LUNETTE, in the Manege, is a half horse-shoe, or such a shoe as wants the sponge, i. e. that part of the branch which runs towards the quarters of the foot.

LUNETTE, is also the name of two small pieces of felt, made round and hollow, to clap upon the eyes of a vicious horse, that is apt to bite, and strike with his fore-feet, or that will not suffer his rider to mount him.

LUNGS, in Anatomy, a part of the human body serving for respiration. In the *Journal de Medecine* for June, 1789, is a description of an instrument for inflating the lungs, invented by M. Gorcey, physician to the military hospital at Newshri-sach, which appears to be extremely well adapted to the purpose, whilst it may be used with the greatest ease and facility. This instrument, which the inventor styles *apodopic*, that is, "restorer of respiration," consists of a double pair of bellows. BCLM, fig. 1, the two different parts of which have no communication with each other. In the lower side BM is an aperture A, for a valve constructed on the principles of those of M'Nairne's air pump. It consists of a rim of copper, closed at one end by a plate of the same metal, in which plate are seven small holes placed at equal distances. This plate is covered with pieces of silk coated with elastic gum, in which are six transverse incisions, of two or three lines in length. Each incision is so made as to be situated between two of the holes, and at an equal distance from each: see D, fig. 2.

The silk must be made very secure by a thread passing several times round the rim. It is obvious, that a stream of air applied to that side of the plate which is opposite the silk, will pass through the holes, and, lifting up the silk, will escape through the incisions. On the contrary, a stream of air applied to the other side will press the silk upon the plate, and thus close the holes, so that it will be impossible for it to pass through them. This valve opens internally, so as to admit the

air from without. At B is another valve, on the same construction, but, opening in a contrary direction, thus permitting the air to escape out of the lower part into the tube EF, but preventing its entrance. At C is another valve, opening internally to admit the air from the tube EF; and at D there is a fourth, opening externally to discharge the air from the upper part. The flexible tube EF, screwed at the end C B, being introduced into one of the nostrils, whilst the mouth and the other nostril are closed by an assistant, if we separate the two handles L M, which were close together at the introduction of the tube, it is evident that the air in the lungs will rush into the upper part through the valve C, whilst the external air will fill the lower

part through the valve A; the two handles being again brought into contact, the atmospheric air will be forced into the lungs through the valve B, and at the same time the air in the upper part will be discharged at the valve D. Thus by the alternate play of the double bellows, the lungs will be alternately filled and emptied as in respiration. In using this instrument, care should be taken not to be too violent; as the more perfectly the natural motion of respiration is imitated, the better. To prevent any substances from without injuring the valves A D, fig. 1, the rim is made with a screw B, fig. 3, in order to receive a cap A A, fig. 3, full of small holes. This screw has also another use. If air, or oxygen gas, be preferred, a bladder, filled with air, fig. 4, may, by means of the screw A, be fastened to the valve A, fig. 1; and, to prevent waste, as this air may serve several times, a flexible tube may be screwed on the valve D, fig. 1, communicating with the bladder by means of the opening d, fig. 4: thus it may be employed as often as the operator thinks proper. There is a handle K to the partition in the middle, in order that, if it be at any time necessary to use either of the divisions alone, the other may be confined from acting. c b, fig. 5, represent the two valves to be applied at the end of the instrument c B, fig. 1; and fig. 6, is a section of the end c B, shewing the valves in their proper places. It is proper to add, that the capacity of the instrument should be proportioned to the quantity of air received into the lungs in inspiration, which Dr. Goodwyn has ascertained to be twelve cubical inches, or somewhat more. Each division of the instrument, therefore, should be capable of containing that quantity.

LUPUS, the Wolf, one of the old constellations, lies on the East of Centaurus, with which it is bounded on the North by Scorpio, and on the West by Norma Euclidis; or, anciently, by Ara, the altar.

LUSTRAL, an epithet given by the ancients to the water used

in their ceremonies to sprinkle and purify the people. From them the Roman church borrowed the holy water.

LUSTRATION, in Antiquity, sacrifices or ceremonies by which the ancients purified their cities, fields, armies, or people defiled by any crime or impurity. Some of these lustrations were public, others private. There were three species of manners of performing lustration, viz. by fire and sulphur, by water, and by air; which last was done by fanning and agitating the air round the thing to be purified.

LUTE, or **LOTINO**, among chemists, a mixed, tenacious, ductile substance, which grows solid by drying, and being applied to the juncture of vessels, stops them up, so as to prevent the air from getting in or out. Lute is also a musical instrument with strings.—The lute consists of four parts, viz. the table, the body or belly, which has nine or ten sides; the neck, which has nine or ten stops or divisions, marked with strings; and the head or cross, where the sorbs for raising and lowering the strings to a proper pitch of tone are fixed. In the middle of the table there is a rose, or passage for the sound. There is also a bridge that the strings are fastened to, and a piece of ivory between the head and the neck, to which the other extremities of the strings are fitted. In playing, the strings are struck with the right hand, and with the left the stops are pressed. The lutes of Bologna are esteemed the best, on account of the wood, which is said to have an uncommon disposition for producing a sweet sound.

LUTHERN, in Architecture, a kind of window over the cornice, in the roof of a building, standing perpendicularly over the naked part of a wall, and serving to illuminate the upper story. Lutherns are of various forms, as square, semicircular, round, called bull's eye, elliptic arches, &c.

LUXATION, is when any bone is moved out of its place of articulation, so as to impede or destroy its proper office or motion.

LYCIUM, a genus of plants belonging to the pentandria class, and in the natural method ranking under the 28th order, Lauræ.

LYCODONTES, the petrified teeth of the *lupus piscis*, or wolf-fish, frequently found fossil. They are of different shapes, but the most common kind rise into a semicircular form, and are hollow within, somewhat resembling an acorn cup; this hollow is found sometimes empty, and sometimes filled with the stratum in which it is immersed. Many of them have an outer circle of a different colour from the rest.

LYCOPERDON, a genus of plants belonging to the cryptogamia class.

LYCOPodium, or **CLUB MOSS**, a genus of plants belonging to the cryptogamia class.

LYCOPSIS, a genus of plants belonging to the pentandria class; and in the natural method ranking under the 41st order, Asperifolia.

LYCOPUS, a genus of plants belonging to the diandria class; and in the natural method ranking under the 42nd order, Verticillate.

LYING-TO, the situation of a ship when she is retarded in her course by arranging the sails in such a manner as to counteract each other with nearly equal effect, and render the ship almost stationary with respect to her head-way; a ship is usually brought to by laying either her main top-sail or fore-top-sail aback, the helm being put close down to leeward. This is particularly practised in a general engagement, when the hostile fleets are drawn up to battle.

LYMPH, a fine fluid, separated in the body from the mass of blood, and contained in peculiar vessels. It is distinguished into watery and coagulable.

LYNX, THE, in Astronomy, is one of the northern constellations, and was composed by Hevelius out of the unformed stars of the ancients.—*Boundaries and Contents*: N. by Ursa Major and Camelopardalis, E. by Leo Minor, S. by Cancer and Gemini, and W. by Auriga and Camelopardalis. There are 44 stars in this constellation, whose right ascension, generally, is 116°, and its declination 45° N. The greater part of it, therefore, does not set to the British isles. None of the stars exceed the 4th magnitude, and their positions may be easily ascertained by reference to the neighbouring constellations. The Lynx is a paratellon to Gemini and Cancer.

LYONS, ISRAEL, a reputable mathematician, and an excellent botanist, was born of Jewish parents in Cambridge, in 1739. He was author of several works, but the only one necessary to mention here is his "Treatise on Fluxions," published in 1758. He was appointed astronomical observer in Captain Phipps's voyage towards the North Pole in 1773; the duties of which office he discharged much to the satisfaction of the Board of Longitude, by whom he was appointed. His death happened about two years after his return from this voyage.

LYRA, *the Harp*, one of the northern constellations, which owes its name to the lyre that Apollo gave to Orpheus, and with which he descended into the infernal regions, in search of Euridice. Orpheus, after death, received divine honours, and his lyre became one of the constellations.—*Boundaries and Contents*: This constellation, situated to the S. E. of the head of Draco, occupies the right angle of a triangle formed by Arcturus, Vega, and the Polar Star on the W.; it is bounded by Hercules S. by E., and E. by Cygnus. Lyra is easily known by *Vega*, of the 1st magnitude, which shines with a splendid white lustre; β , γ , δ , are also conspicuous stars, of the 2d and 4th magnitudes. *Vega*, α , having $277^{\circ} 42' 36''$ right ascension, and $38^{\circ} 37' 22''$ north decli-

nation, never sets to the British isles, and it culminates as follows: Merid. Alt. $77^{\circ} 6' 22''$ N.

MONTH.	CULM. ho. mi.	MONTH.	CULM. ho. mi.	MONTH.	CULM. ho. mi.

LYRE, a musical instrument of the stringed kind, much used by the ancients.

Concerning the number of strings with which this instrument was furnished, there is great controversy. Some assert it to be only three; and that the sounds of the two remote were acute, and that of the intermediate one, a mean between those two extremes; that Mercury, the inventor, resembled those three chords to as many seasons of the year, which were all that the Greeks reckoned, namely, summer, winter, and spring; assigning the acute to the first, the grave to the second, and the mean to the third.

LYTHRUM, *Purple Loosestrife*, a genus of plants belonging to the decandria class; and in the natural method ranking under the 17th order, Calycanthemæ. See BOTANY.

M.

M A C

M A C

M is the twelfth letter of our alphabet. M is also a numeral letter, and among the ancients was used for a thousand. When a dash is added to the top of it, as \overline{M} , it signifies a thousand times a thousand. M, as an abbreviation, stands for Manlius, Marcus, Martius, and Mucius; M. A. signifies magister artium, or master of arts; MS. manuscript; and MSS. manuscripts. M in astronomical tables, and other things of that kind, is used for meridional or southern, and sometimes for meridian or mid-day. M.D. medicus doctor, doctor of medicine. M, in medicinal prescription, is frequently used to signify a maniple or handful; and it is sometimes also put at the end of a recipe, for *mixce*, "mingle;" or for *mixture*, "a mixture." Thus, *m. f. julapium*, signifies "mix and make a julep." M, in Law, the brand or stigma of a person convicted of manslaughter, and admitted to the benefit of clergy. It is to be burnt on the brawn of his left thumb.

MABBY, a species of wine made from potatoes. Some attempts have recently been made to improve its quality, but without much success. It is said to be in use in Barbadoes.

MAC, an Irish word signifying son. It is frequently prefixed to surnames, as *Macdonald* for Donald's son; *MacLaurin*, for the son of Laurin or Laurence.

MACAM, in Natural History, the name of an Indian fruit. It is of a round shape, and about the size of our common wild crabs which grow in the hedges. Instead of seeds resembling apples, it has one hard kernel: the taste is unpleasant. The tree is small, and its leaves appear like those of the quince, having somewhat of a yellowish tinge.

MACARONIC, or **MACARONIAN**, an appellation given to a barlesque kind of poetry, made up of a jumble of words of different languages, and words of the vulgar tongue latinized. The Italians are said to have been the inventors of it. The Germans, French Spaniards, &c. have also had their macaronic poets.

MACASSAR POISON, called in natural history, *ippo*, is the gum of a tree that grows in the isle of Celebes, in the Indian Ocean, with which the Malaysians anoint their arrows.

MACE, the covering of the nutmeg, that lies between the outer coat and the shell. It is an unctuous membrane; first of a light red, and afterwards, when dried as we see it, of a yellowish hue. After being taken from the shell and exposed to the sun, it is dipped in sea water, or moistened with it, and finally so far dried as to allow of its being packed in bales for exportation.

MACE is liable to seizure, if packed in bales of less than 300 lbs weight. It possesses all the virtues, without the astringency, of the nutmeg.

MACERATION, in Pharmacy, an infusion or soaking ingredients in water, or other fluid, in order to soften them, and draw out their virtues.

MACHINE, signifies any thing used to augment or regulate moving forces or powers; or it is any instrument employed to produce motion in order to save either time or force. The word is of Greek origin, and implies *machine*, *invention*, *art*; is therefore properly applied to any agent, in which these are combined, whatever may be the strength or solidity of the materials of which it is composed. The term *machine*, is, however, generally restricted to a certain class of agents, which seem to hold a middle place between the most simple tools or instruments, and the more complicated and powerful engines; this distinction, however, has no place in a scientific point of view; all such compound agents being generally classed under the term machines, the simple parts of which they are compounded, being termed **MECHANICAL POWERS**. Machines are again classed under different denominations, according to the agents by which they are put in motion, the purposes they are intended to effect, or the art in which they are employed; as, *Electric*, *Hydraulic*, *Pneumatic*, *Military*, *Architectural*, &c. **MACHINES**.

The maximum effect of machines is the greatest effect which can be produced by them. In all machines, working with an uniform motion, there is a certain velocity and a certain load of resistance, that yield the greatest effect, and which are therefore more advantageous than any other. A machine may be so heavily charged, that the motion resulting from the application of any given power will be only sufficient to overcome it, and if any motion ensue, it will be very trifling, and the effect small. Again, if the machine is very lightly loaded, it may give great velocity to the load; but from the smallness of its quantity, the effect may still be very considerable, consequently between these two loads there must be some intermediate one, that will render the effect the greatest possible. And this is equally true in the application of animal strength as in machines, and both have been submitted to strict mathematical investigation, the former being founded on numerous experiments and observations on the best method of applying animal strength, and the measure of it when applied in different directions.

produce is from 30,000 to 40,000 gallons of water per hour. We may mean produce, because, under certain favourable circumstances, it raises more than 60,000 gallons per hour. But during inundations, or when the Seine is frozen, when the water is very low, or when any repairs are making, the machine stops in great measure, if not entirely. The annual expense of the machine, including the salaries of men, &c. is about £9 a day.

MACLAURIN, COLIN, a very celebrated mathematician, was born in Argyllshire, in February 1724. In his 12th year he is said to have made himself master of the first six books of Euclid in a few days without any assistance, having met with the book by accident, and studied as it were for his amusement. — In 1747 he was appointed professor of mathematics in the Marischal college, Aberdeen, and was soon after admitted a fellow of the Royal Society, of which he was a very useful member. He died in June, 1748, in the 48th year of his age. He was a good as well as a great man, beloved and admired by the greatest geniuses of his time, by Newton, Hoadly, Clarke, Folkes, Bari Morton, &c.

MACULÆ, in Astronomy, dark spots appearing in the luminous faces of the sun, moon, and even some of the planets. In this sense the maculæ stand contradistinguished from the faculæ, which are luminous spots. The solar maculæ are of an irregular changeable figure, observed first by Galileo in 1610, soon after he had finished his telescope, and about the same time by Huygens and Hovellius, Mr. Flamsteed, Cassini, Kirch, &c. Many of these maculæ appear to consist of heterogeneous parts, of which the darker and more dense are called by Hovellius nuclei, and are encompassed as it were with atmospheres somewhat rarer, and less obscure, but the figure both of the nuclei and entire maculæ is variable. In 1644 Hovellius observed a small thin macula, which in two days extended ten times its bulk, appearing withal much darker, and with a larger nucleus; and such sudden mutations are frequent. The nucleus began to fail sensibly before the spot disappeared, and before that it quite vanished it broke into four, which in two days again re-united. Some maculæ have lasted fifteen, twenty, thirty, but seldom forty days; though Kirch observed one in 1681, which remained from April 20th to the 17th of July. The spots move over the sun's disc with a motion somewhat slower nearer the limb than the centre. That observed by Kirch was twelve days visible on the sun's disc; for fifteen days more it lay behind it, it being usual to return to the limb whence they departed, in twenty-seven, and sometimes in twenty-eight days. The different figures of the solar spots, varying from the circular form to the respective widths of an elliptical shape, is produced by the gradual recession of the same spots from the middle or front of the sun's disc to his edge, by the rotation of this star on its axis. Various hypotheses have been invented to account for these spots; some considering them as dark clouds floating in the solar atmosphere, others as real excavations, which have not the property of propagating light as the other parts of this luminary, the depth of some of them having been estimated at more than 4000 miles, and their orifices much exceeding this in diameter; some of them, indeed, from the angle they subtend, must exceed in size the whole globe of the earth.

Dr. Herschel has offered some conjectures on this subject, in the Philosophical Transactions for 1795 and 1801; those variations in the state of the weather, in different years, may arise, he thinks, from the greater or less number of maculæ on the solar disc.

MADDER, a rough trailing plant, that grows wild in the south of Europe, and is much cultivated in England and Holland as a dye-wood for calico printers. The roots afford the dye. But the madder of Smyrna and Cyprus excels for its bright and beautiful red colour. The roots of the plant, after being dug up, are carefully peeled, and dried in an open airy shade, and afterwards in a kiln, in the same way as hops are dried in Kent. The next process, of pulverizing or chopping them, was long a secret with the Dutch; but we have machines now in Glasgow and Manchester, that do this in the most superior style.

MADREPORÆ, in Natural History, the name of a genus of submarine substances, belonging to the order Altophyte.

MADRIGAL. A short amorous poem of unequal verses,

not confined either to the regularity of a sonnet, or to the point of an epigram. A beautiful, noble, and delicate thought, expressed with elegant simplicity, falls under this denomination.

MAGAZINE, a place in which stores are kept, of arms, ammunition, provisions, &c.

MAGAZINE, Powder, ought to be fire and bomb proof; semi-circular, 60 feet within the foundations, being 8 feet thick, and 8 high to the spring of the arch.

MAGAZINE, Artillery, in a siege, is made about 25 or 30 yards behind the battery, towards the parallels, and at least 3 feet under ground.

MAGAZINE, is also a term applied to a periodical publication; as, the *Imperial Magazine*, the *Philosophical Magazine*, &c. The number of these monthly publications is very great, and the knowledge they diffuse is proportionate to their numbers.

MAGELLANIC CLOUDS, the name given to three permanent whitish appearances, resembling the milky way, near the south pole, being distant from it about 11 degrees.

MAGI, or **MAGIANS**, an ancient religious sect in Persia, and other eastern countries, who maintained, that there were two principles, the one the cause of all good, the other the cause of all evil; and, abominating the adoration of images, worshipped God only by fire, which they looked upon as the brightest and most glorious symbol of Oromasdes, or the Good God; as darkness is the truest symbol of Arimanius, or the Evil God. This religion was reformed by Zoroaster. The sect still subsists in Persia, under the denomination of *Gours*.

MAGIC, originally signified only the knowledge of the more sublime parts of philosophy; but as the magi likewise professed astrology, divination, and sorcery, the term magi became odious, being used to signify an unlawful, diabolical kind of science, acquired by the assistance of the devil and departed souls. Natural magic is only the application of natural philosophy to the production of surprising but yet natural effects.

Magic Square, is a square divided into cells, in which the natural numbers from 1 to the proposed square are so posited, that the sum of each row, whether taken horizontally, vertically, or diagonally, is equal to a certain given number; thus, in the annexed figure, which contains 9 cells, the sum of the numbers in each row is equal to 15.

De Lahire gives the following rule for filling up the cells in any square consisting of an odd number of units, viz.

22	47	16	41	10	35	4
5	23	48	17	42	11	29
30	6	24	49	18	36	12
13	21	7	25	43	19	37
28	14	22	1	26	44	20
21	20	8	32	2	27	45
46	15	40	9	31	3	28

Place the least term 1, in the cell immediately under the middle or central one, and the rest of the terms, in their natural order, in a descending diagonal direction, till they run off either at the bottom or on the side. When the number runs off at the bottom, carry it to the uppermost cell which is not occupied, of the same column that it would have fallen in below, and then proceed, descending diagonally again as far as you can, or till the numbers either run off at the bottom or side, or are interrupted by coming at a cell already filled. When any number runs off at the right hand side, then bring it to the farthest cell on the left hand of the same row or line it would have fallen in towards the right hand; and when the progress diagonally is interrupted, by meeting with a cell already occupied by some other number, then descend diagonally to the left from this cell till an empty one is met with, where enter; and thence proceed as before. This rule, with reference to the above square, will be readily understood by the ingenious reader without further explanation.

Magic Square of Squares, is an extension given to the magic square, by Dr. Franklin. Here a great square of 256 little squares, in which all the numbers from 1 to 16² or 256, are placed in 16 columns, which, taken either horizontally or ver-

tically, possess several curious properties but which we are obliged to omit detailing, for the introduction of more important matter.

Magic Circle of Circles, is an invention of Dr. Franklin & founded on the same principles and possessing similar properties to the magic square of squares, by the same author. This consists of eight concentric circles and eight radii, the circumferences of which all the natural numbers from 12 to 72 are so posited, that the sum of the numbers in each circumference together with the central number 12, is equal to 360; and the numbers in each radius, including always the central number, also is equal to 360. Besides the above, these circles possess several other curious properties. The position of the numbers in each radius is as below, beginning with the outward number, and proceeding thence towards the centre, which is always 12, and common to each radius:

1st rad.	2d rad.	3d rad.	4th rad.	5th rad.	6th rad.	7th rad.	8th rad.
62	73	14	25	36	47	58	69
24	15	72	63	54	45	36	27
71	64	23	16	35	28	57	50
17	22	65	70	42	39	30	21
60	66	31	18	37	34	53	56
19	20	67	68	51	52	43	32
60	75	12	27	26	48	44	59
29	13	74	61	55	46	37	28
12	12	12	12	12	12	12	12

Here the successive horizon lines will represent the several circumferences, and the vertical ones the radii, the sum in each being 360.

MAGNA CHARTA, the great charter of the liberties of England, and the basis of our laws and privileges. It was first obtained by the barons, sword in hand, from King John, and was ratified by various subsequent kings.

MAGNESIA. This is a family of minerals which comprehends all the combinations of magnesia with acids. When freed from extraneous matters, magnesia is a powdery substance of a limpid white colour.

Epsom Salts, or **Sulphate of Magnesia**, consists of magnesia in conjunction with sulphuric acid. It is said, that Epsom salts have been found in the Alps and in Switzerland under a powdery form, and sometimes even in masses, or in a state of incrustation on stones and rocks. They are, however, chiefly found dissolved in mineral waters, and particularly in those at Epsom in Surrey and Seiditz in Bohemia. Their taste is bitter and unpleasant. So little are they affected by exposure to the air, that the Abbé Haüy kept some by him for more than 25 years without any sensible alteration. These salts are much used in medicine, and are sometimes manufactured from the waters of Epsom and Seiditz, but more frequently and in a more greater abundance from sea water. The magnesia of the shops is prepared by dissolving Epsom salts in water, and adding to the solution half their weight of potash. The substance that sinks to the bottom is carbonate of potash, washed with a sufficient quantity of water and dried, has the appearance of a light, soft, and white powder, of a limpid taste. Magnesia is used in medicine, both in a crude state and when calcined or burnt. It is also employed in some chemical processes; and is in considerable request in the manufacture of enamel and porcelain. If putrid water be agitated with a small quantity of magnesia, it will lose a considerable portion of its bad taste and smell.

MAGNET, **LOADSTONE**, a ferruginous stone, which is endowed with the property of attracting iron, of pointing itself in a certain direction, and of communicating the same property to iron or steel bars. See MARINER'S COMPASS.

The Poles of a MAGNET, are those points which seem to possess the greatest power, or in which all the virtue appears to be concentrated. The **Magnetical Meridian**, is a vertical circle in the heavens, which intersects the horizon in the points to which the magnetic needle when at rest directs itself. The **Axis of a Magnet**, is a right line which passes from one pole to another. The **Equator of a Magnet**, is a line perpendicular to the axis, and exactly between the poles.

The distinguishing and characteristic properties of a magnet are as follows:—1. Its attractive and repulsive power. 2. Its

directional power. 3. Its ability in communicating to a point above or below the horizon, a like power of communicating its own properties to several other bodies.

Properties of the Magnet.—These are numerous, but some of the principal are as follows:—1. A magnet, when freely supported by a thread, or in a light vessel of water, will place itself in a direction nearly coinciding with the poles of the earth. 2. The direction of the needle is not the same in all parts of the world, nor in the same place at different times. 3. A needle, not magnetized, being exactly balanced, will, if touched by a magnet, so as to communicate that property to it, take its equilibrium destroyed, one of its extremities dipping considerably below the horizontal plane. 4. The centres of action of a magnet are at a small distance from its extremities, and the law of attraction from these centres is reciprocally as the squares of the distances. 5. When a magnetic needle is out of its natural line of direction, the force with which it tends to return that position varies as the sine of the angle between the natural direction and that in which it is placed. 6. In every magnet there are two poles, of which the one attracts iron wires, the other repels them; and if the magnet be divided into any number of pieces, the two poles will be found in each piece. The poles of a magnet may be found by holding a very fine silver needle over it, for where the poles are, the needle will stand upright, but not where else.

Thus in fig. 1. of the horse-shoe magnet, N indicates the north, and S the south pole of the magnet. By the following method, also, the situation of the poles, and the direction of the supposed magnetic effect, passing out of the stone, may be ascertained.—Screw about the poles of the stone on every side, little circular pieces of a sheet of white paper; these small particles will be affected by the effluvia of the stone, and be so disposed as to show the course and direction of the magnetic particles in every part. Thus in fig. 2. in the middle of each pole,

Fig. 1.

Fig. 2.

it appears to gradually converge towards the sides it produces a series of more and more pointed, till at last the curves form from both poles exactly meeting and encircling, form complete circles on each side, being of a circular figure.

A small circular magnet may be used in this experiment, instead of the horse-shoe magnet, with a similar effect, if the table on which the paper rests receives a few gentle knocks, so as to shake the filings a little, otherwise the action of the magnet will not be sufficient to dispose properly these particles which lie at a considerable distance.

7. Three poles, in different parts of the globe, are differently directed towards a point under the horizon. 8. These poles, though contrary to each other, help mutually towards the magnetic attraction, and suspension of iron. 9. If two magnets be spherical, one will turn or conform itself to the other, as either of them would do to the earth; and after they have so conformed or turned themselves, they have a tendency to approach or join each other; but if placed in a contrary position, they repel each other. 10. If a magnet be cut through the axis, the segments or parts of the stone, which before were joined, will now repel each other. 11. If the magnet be cut perpendicular to its axis, the two points which were before conjoined, will become contrary poles, one in the one, and one in the other segment. 12. Iron receives virtue from the magnet by application to it, or barely from an approach towards it, though it do not touch it; and the iron receives its virtue variously, according to the parts of the stone it is made to touch, or even approach to. 13. If an oblong piece of iron be any way applied to the stone, it receives virtue from it only lengthways. 14. A needle touched by a magnet will turn its

end the same way, towards the poles of the world, as the magnet itself does. 15. Neither the magnet, nor needles touched by it, conform their poles exactly to those of the world, but have usually some variation from them; and this variation is different in different places, and at divers times in the same places. 16. A magnet will take up much more iron, when armed or capped, than it can alone. 17. A strong magnet at the least distance from a smaller or a weaker, cannot draw to it a piece of iron adhering actually to such a smaller or weaker stone; but if it touch it, it can draw it from the other: but a weaker magnet, or even a small piece of iron, can draw away or separate a piece of iron, contiguous to a larger or stronger magnet. 18. In north latitudes the south pole of a magnet will raise up more iron than its north pole. 19. A plate of iron only, but no other body interposed, can impede the operation of the magnet, either as to its attractive or directive quality.

20. The power or virtue of a magnet may be impaired by lying long in a wrong position, as also by rust, wet, &c. and may be quite destroyed by fire, lightning, &c. 21. A wire being touched from end to end with one pole of a magnet, the end at which you begin will always turn contrary to the pole that touched it; and if it be again touched the same way with the other pole of the magnet, it will then be turned the contrary way. 22. If a piece of wire be touched in the middle with only the pole of the magnet, without moving it backwards or forwards, in that place will be the pole of the wire, and the two ends will be the other pole. 23. If a magnet be heated red-hot, and again cooled, either with its south pole towards the north, in a horizontal position, or with its south pole downwards in a perpendicular position, its poles will be changed. 24. Hard iron tools well tempered, when heated by a brisk attrition, as filing, turning, &c. will attract thin filings, or chips of iron, steel, &c. and hence we observe that files, punches, augers, &c. have a small degree of magnetic virtue.

25. The iron bars of windows, &c. which have stood a long time in an erect position, grow permanently magnetical; the lower ends of such bars being the north pole, and the upper end the south pole. 26. Tonga and fireforks, by being often heated, and set to cool again, in a posture nearly erect, have gained this magnetic property. Sometimes iron bars, by long standing in a perpendicular position, have acquired the magnetic virtue in a surprising degree. A bar about ten feet long and three inches thick, supporting the summer beam of a room, was able to turn the needle at eight or ten feet distance, and exceeded a loadstone of three pounds and a half weight; from the middle point upwards it was a north pole, and downwards a south pole.

27. A needle well touched, it is known, will point nearly north and south; but if it have one contrary touch of the same stone, it will be deprived of its faculty, and by another such touch it will have its poles interchanged.

28. A magnet acts with equal force in vacuo as in the open air. The smallest magnets have usually the greatest power in proportion to their bulk. A large magnet will seldom take up above three or four times its own weight, while a small one will often take up more than ten times its weight. A magnet worn by Sir Isaac Newton in a ring, and which weighed only 3 grains, would take up 746 grains, or almost 250 times its own weight. A magnetic bar made by Mr. Canton, weighing 10 oz. 12 dwts. took up more than 70 ounces; and a flat semi-circular steel magnet weighing 1 oz. 13 dwts. took up an iron wedge of 80 ounces.

Armed Magnet, denotes one that is capped, cased, or set on iron or steel, to make it take up a greater weight, and also more readily to distinguish its poles. The magnet in this case is mounted with two pieces of iron, which are called the armature. The figure represents an armed magnet, where A B is the loadstone; C D, C D, are the armature, or the two pieces of soft iron, to the projections of which, D, D, the iron weight it is to be applied. The dots E, L, d, L, d, represent the brass box, with a ring at E, by which the armed magnet may be suspended.

Artificial Magnet, is a bar of iron or steel impregnated with the magnetic fluid, and possessing all the properties of the magnet itself, and commonly in a much higher degree. There are various methods of communicating the power of a magnet to bars of iron and steel, whereby these last become themselves magnets, and capable of again transmitting their power to others, and so on. There are also several ways of making artificial magnets without the assistance of any magnet whatever. Procure a dozen bars, six of soft steel and six of hard; the former to be each three inches long, $\frac{1}{4}$ of an inch broad, and the 20th of an inch thick, with two pieces of iron, each half the length of one of the bars, but of the same breadth and thickness, and the six hard bars to be each 5 $\frac{1}{2}$ inches long, $\frac{1}{4}$ an inch broad, and $\frac{3}{16}$ ths of an inch thick, with two pieces of iron half the length, but the whole breadth and thickness, of one of the hard bars; and let all the bars be marked with a line quite round them at one end. Then take up an iron poker and tongs, or two bars of iron, the larger they are and the longer they have been used, the better; and fixing the poker upright between the knees, hold to it near the top, one of the soft bars, having its marked end downwards, by a piece of sewing silk, which must be pulled tight by the left hand, that the bar may not slide; then grasping the tongs with the right hand a little below the middle, and holding them nearly in a vertical position, let the bar be stroked by the lower end from the bottom to the top, about ten times on each side, which will give it a magnetic power sufficient to lift a small key at the marked end, which end, if the bar were suspended on a point, would turn towards the north, and is therefore called the north pole; and the unmarked end is for the same reason called the south pole: four of the soft bars being impregnated after this manner, lay two of them parallel to each other, at one-fourth of an inch distance, between the two pieces of iron holding them, a north and south pole against each piece of iron; then take two of the four bars already made magnetical, and place them together so as to make a double bar in thickness, the north pole of one even with the south pole of the other; and the remaining two being put to these, one on each side, so as to have two north and two south poles together, separate the north from the south poles at one end by a large pin, and place them perpendicularly with that end downwards on the middle of one of the parallel bars, two north poles towards its south end, and the two south poles towards its north end; slide them three or four times backward and forward the whole length of the bar; then removing them from the middle of this bar, place them on the middle of the other bar, as before directed, and go over that in the same manner; then turn both the bars the other side upwards, and repeat the former operation; this being done, take the two from between the pieces of iron, and placing the two outermost of the touching bars in their stead, let the other two be the outermost of the four to touch these with; and this process being repeated till each pair of bars have been touched three or four times over, will give them a considerable magnetic power. Put the half dozen together after the manner of the four, and touch them with two pair of the hard bars placed between their irons, at the distance of about half an inch from each other; then lay the soft bars aside, and with the four hard ones let the other two be impregnated, holding the touching bars apart at the lower end near two-tenths of an inch; to which distance let them be separated after they are set on the parallel bar, and brought together again before they are taken off: this being observed, proceed according to the method described above, till each pair has been touched two or three times over; but as this vertical way of touching a bar will not give it quite so much of the magnetic virtue as it will receive, let each pair be now touched once or twice over, in their parallel position, between the irons, with two of the bars held horizontally, or nearly so, by drawing at the same time the north end of one from the middle over the south end, and the south of the other from the middle over the north end of a parallel bar; then bringing them to the middle again without touching the parallel bar, give three or four of these horizontal strokes to each side. The horizontal touch, after the vertical, will make the bars as strong as they possibly can be made, as appears by their not receiving any additional strength, when the vertical touch is given by a great

number of bars, and the horizontal by those of a superior magnetic power.

This whole process may be gone through in about half an hour; and each of the large bars, if well hardened, may be made to lift twenty-eight Troy ounces, and sometimes more. And when these bars are thus impregnated, they will give to a hard bar of the same size its full virtue in less than ten minutes; and therefore will answer all the purposes of magnetism in navigation and experimental philosophy, much better than the loadstone, which has not a power sufficient to impregnate hard bars. The half dozen being put into a case in such a manner as that no two poles of the same name may be together, and their irons with them as one bar, they will retain the virtues they received; but if their power should, by making experiments, be ever so far impaired, it may be restored without any foreign assistance in a few minutes. And if perchance a much larger set of bars should be required, these will communicate to them a sufficient power to proceed with; and they may in a short time, by the same method, be brought to their full strength.—*Barlow, Phil. Tran.*

To illustrate the magnetical inclination or dip of the needle, take a globular magnet, or, which is more easily procured, an oblong one, like S. N. in the figure; the extremity N, of which

is the north pole; the other extremity, S, is the south pole, and A is the middle or equator; place it horizontally upon a table C D, then take another small oblong magnet, *n. z.* a bit of steel wire, or a small sewing needle magnetized, and suspend it by means of a fine thread tied to its middle, so as to remain in an horizontal position when not disturbed by the vicinity of iron, or other magnet. Now, if the same small magnet being held by the upper part of the thread, be brought just over the middle of the large magnet within two or three inches of it, the former will turn its south pole *s*, towards the north pole N of the large magnet, and its north pole *n* towards the south pole S of the large one. It will be farther observed, that the small magnet, while kept just over the middle of the large one, will remain parallel to it; for since the poles of the small magnet are equally distant from the contrary poles of the large magnet, they are equally attracted. But if the small magnet be moved a little nearer to one end than to the other of the large magnet, then one of its poles, *viz.* that which is nearest to the contrary pole of the large magnet, will be inclined downwards, and of course the other pole will be elevated above the horizon. It is evident that this inclination will increase according as the small magnet is placed near to one of the poles of the large one, because the attraction of the nearest will have more power upon it. If the small magnet be brought just opposite to one of the poles of the large magnet, it will turn the contrary pole towards it, and will place itself in the same straight line with the axis of the large magnet.

This simple experiment will enable the reader to comprehend easily the phenomena of the magnetic inclination, or of the dipping needle upon the surface of the earth; for it is only necessary to imagine, that the earth is a large magnet, (as it in fact appears to be,) and that any magnet, or magnetic needle commonly used, is the small magnet employed in the foregoing experiment. The direction of the dipping needle in any place is called the *magnetic line*.

The best shape of a magnetic needle is represented in these two figures, the first of which shows the upper side, and the second shows a lateral view of the needle, which is made of steel, having a pretty large hole in the middle, to which a conical piece of agate is adapted by means of a brass

piece O, into which the agate is fixed. The apex of this hollow cap rests upon the point of a pin F, which is fixed to the centre of the box, and upon which the needle, being properly balanced, turns very nimbly. For common purposes, these needles have a conical perforation made in the steel itself, or in a piece of brass, which is fastened in the middle of the needle.

The dipping needle, though of late much improved, is however still far from perfection. The general mode of constructing it is, to pass an axis quite through the needle, to let the extremities of this axis, like those of the beam of a balance, rest upon its supports, so that the needle may move itself vertically round, and, when situated in the magnetic meridian, it may place itself in the magnetic line. The degrees of inclination are shewn upon a divided circle, in the centre of which the

needle is suspended. This figure represents a dipping needle of the simplest construction:—A B is the needle, the axis of which F E rests upon the middle of two lateral bars C D, C D, which are made to the frame that contains the divided circle A I B K. This machine is fixed on a stand O, but when used at sea it is suspended by a ring H, so as to hang perpendicularly. When the instrument is furnished with a stand, a spirit level O is generally annexed to it, and the stand

has three screws, by which the instrument is situated, so that the centre of the needle, and the division of 90 on the lower part of the divided circle, may be exactly in the same time perpendicular to the horizon.

An Account of the Experiments of Peter Barlow, of the Royal Military Academy, on the Magnetism induced or exhibited in Iron and other Metals by rotation.

Availing himself of one of the turning lathes, in the royal arsenal, an attempt was made by this gentleman to ascertain whether, by giving to an iron body a rapid rotation, any change could be distinguished in its magnetic state during the motion, or after it had subsided; accordingly, a small howitzer shell was attached to a lathe, admitting of a rapid motion, and a small compass being placed very near to it, it was perceived at once that the needle was considerably deflected, but it returned to its original direction as soon as the motion ceased. A thirteen-inch shell was then fixed to the mandrel of one of the large lathes worked by the steam engine, and the effect obtained was of course proportionably greater. In fact, with this shell, the direction of the needle was, in many cases, reversed by the motion of the former; but there were other points in which no motion could be observed.

Moreover, in several instances the deviation of the needle was made in a contrary way to what it was in others, varying in quantity as stated above, from zero to 180°, according to the situation of the needle; the distance and the rate of motion being the same. In all cases, by reversing the motion of the shell, the deviation was reversed also; so that if with the shell turning one way, the needle deviated to the east, it deviated to the west when the shell was turned in an opposite direction; and in all cases during the rotation of the shell, the needle preserved its deviating direction remarkably steady, viz. without any kind of oscillation or tremor; but the moment the motion ceased, it returned to its original and true bearing. The effect produced was therefore temporary, and depended entirely on the velocity of rotation.

These were all the deductions of any importance drawn from the first series of experiments; and as the steam-engines were not set to work again for some time, no farther observations were made, till Mr. Barlow, finding himself embarrassed with the iron work of the lathes and other machines, had an apparatus constructed, which he erected on his own premises, and by means of which he at length succeeded in deducing the laws which regulate and determine the direction of the needle in all cases, and in all situations. The results have been presented to the Royal Society, and the following concise account of them may be acceptable to our readers:—

This apparatus consists of a frame, *a*, resembling that on which the cylinder of an electrical machine is hung; the ball *B* supplying the place of the cylinder, the diameter of the ball or shell was eight inches, and its weight about 30 lb. A strong table *c*, fixed with its feet into the ground, the floor of the room being cut away so as to prevent any shaking of the floor or walls. The diameter of the larger wheel *D* was 14 inches; of the smaller *E*, three inches; and the handle *F* might be turned with ease twice in a second, which gave about 720 revolutions per minute to the shell. A stand *G*, made heavy by being loaded with sand, had a small platform *H* attached; it might be brought up close to the shell, and the suspended compass *I*, surrounded by a glass tube *K*, placed near the same, at any azimuth, and on either side. Moreover, there were several holes in the table, which enabled the experimenter to screw down the frame itself in any azimuth, by means of the fly nuts *L*. The ball could only revolve with its axis horizontal, but it could be made to revolve direct or reverse at pleasure. The platform might be depressed or raised to any height, and the needle thus placed over or under any proposed point of the shell.

Things being thus prepared, the platform was first placed in the horizontal plane of the ball's axis, and the needle placed successively at every point all round. And it appeared that whatever might be the azimuth of the needle, (provided it was neutralized by the magnet, *L*, from the directive power of the earth,) on turning the ball, the north end of the needle approached towards it when the motion was towards the needle, but receded when the motion was from the needle. That is, when the upper part of the shell, by the revolution, descended towards the needle, the north end of the needle approached towards the shell; but when the ball revolved in an opposite direction, then the south end of the needle approached, or the north end receded.

When the needle was carried round the shell in a vertical circle, ascending 10° each time, the following results were observed, (the needle being in every case neutralized, and placed parallel to the axis of rotation,) viz. from the horizon to an altitude of about 54° , the needle placed itself perpendicularly to the axis of the north end, passing the contrary way to that in which the motion of the shell was made; from 54° to 90° , or to the zenith of the ball: the needle also placed itself perpendicularly to the axis, but in a reversed position to what it took up before, viz. the north end passed in the direction of motion in the shell. It did the same on the other side of the vertical, to a like point or altitude of about 54° ; but from that point to the horizon it arranged itself as at first. Below the horizon it also preserved the same direction till it amounted again to 54° ; it then changed its direction, as when above the horizon. There were, therefore, four points of change in the direction of the needle, (the motion of the ball remaining the same,) viz. at 54° above and below the horizon of the ball, on each side of the zenith and nadir. It will of course be understood, that by reversing the motion of the ball, the needle also changed its direction, but the points of change remained the same; and that the effect was independent of the direction of the axis of motion, viz. whether the axis was east and west, north and south, or in any other azimuth; but it required a certain velocity, not less than 600 revolutions per minute, to produce the full effect. It is obvious, therefore, that the more rotation of an iron shell impresses upon it, during the motion of the same, a temporary magnetic effect, and that this effect ceases the moment the motion is discontinued.

The above experiments were begun in December, 1824; and it was not till April 1825, that Mr. Barlow learned that M. Arago had been making similar experiments in France, on copper and other metals, without being aware of their actual date. They were not known in England till Gay Lussac's visit to London at the time above stated. We are not aware of the precise nature of these experiments, and shall, therefore, only endeavour to describe those which Mr. Maish assisted Mr. Barlow in making, and which he founded on the description he had received. They may, therefore, be considered as the experiments of M. Arago, repeated and varied as different circumstances occurred, to suggest new ideas. The account he had of M. Arago's experiments, was, that by placing a copper plate upon a vertical spindle, the plate being horizontal, and then placing just above it a light compass needle, but independent of course of the plate, or causing the spindle and plate to revolve, the needle was considerably deflected, and more and more as the velocity was increased, so that when the plate was put into rapid rotation, the needle also began after a few vibrations to revolve, and at length with considerable velocity.

1. In order to repeat this experiment, says Mr. Maish, I connected the wheel of my turning lathe with a vertical spindle, which I could make revolve forty-five times per second; and on this I placed a thin copper plate, about six inches diameter, and over this a needle about five inches long shut up in a close box, about one inch or rather less above the plate. When putting the lathe in motion, I found it to deflect the needle about five points, the deflection being always in the same direction as the motion of the plate, but we could not cause it to revolve. The needle was therefore partly neutralized by a bar magnet, and the experiment repeated. We then very soon obtained a considerable rotatory motion in the needle; and by using a larger and heavier plate, the same was produced afterwards without neutralizing the needle.

2. Another experiment, which was mentioned as one of M. Arago's, and which I repeated, was by interposing a plate of iron between the copper plate and the needle. In this case no effect could be produced on the needle by the rotation of the copper plate, the iron clearly intercepting the motion.

3. I now tried a zinc plate instead of a copper plate, and the effect was nearly the same as before, but a little less.

4. An iron plate was now substituted, and the effect was considerably greater than with the copper-plate.

5. The copper plate was again replaced, and a brass needle placed in the box. Some motion was obtained, but it was very equivocal, so that I cannot venture to say that it was certainly due to the rotation.

6. A heavy horse-shoe magnet was now suspended by a line from the ceiling, and it was put in rotation by the revolution of the copper plate—a paper screen having been first interposed between them.

7. One copper plate was suspended over another, but no motion was obtained, and the same took place when the copper plate was suspended over an iron one.

8. A bar magnet rather shorter than the diameter of the copper plate was fixed horizontally to the upright spindle, and being made to revolve, the plate very soon acquired rotation. A paper screen was in this, as in the preceding experiments, interposed between the plate and magnet.

9. The plate was now applied immediately to the axis of the lathe, so as to cause it to revolve vertically, and the needle placed near to it, but no motion took place, till, by nearly neutralizing the needle, and bringing either of its poles directly to the plate, it then always deviated in the direction of the motion of the plate, whichever pole of the needle was directed to the former; the needle of course, therefore, deviated different ways, (all other things being the same,) when it was above or below the axis, but in the direct horizontal line of the axis no motion in the needle took place.

10. The above are the principal experiments that I assisted in making by revolving the plate, but these having suggested to Mr. Barlow that all the results obtained might be explained by supposing that there existed a slight magnetic power in copper, and in the various metals, which had a tendency to draw the needle after the plate, or the latter after the former, he endeavoured to exhibit this by direct experiment, independent of

facilitated by a table for this purpose prepared by Mr. Barlow. When this is done, the needle will remain active and vigorous in the polar regions, and will direct itself in the true magnetic meridian, in whatever part of the world the ship is placed. This effect of the invention has been experimentally established between the 61° of south latitude and the 81° of north latitude, by the accurate observations of Lieutenant Foster, and by other naval officers. There are few scientific inventions of modern times more useful in practice than this.

Scoreby's New Experiments on Magnetism, are as follows:—Bars of steel could be rendered highly magnetic by hammering them in a vertical position, with the lower end resting upon a poker or rod of iron. This process, however, he has greatly improved by hammering the steel bars between two bars of iron: the steel bars were the eighth part of an inch in diameter. When only one bar of iron was used, a steel wire six inches long lifted a nail weighing 186 grains; but when two bars of iron were used, the wire lifted 326 grains. When the new process was employed with an iron bar eight feet long, a steel wire six inches long lifted 669 grains, or four times its own weight. The theory of the process is, that percussion on magnetizable substances in mutual contact inclines them to an equality of condition, in the same manner as all bodies of different temperatures tend to assume the same temperature when in contact. The two great iron bars being made magnetic by position, the interposed bar of steel will therefore, when thrown into a state of vibration by percussion, receive a portion of their magnetism. In like manner a magnet, when struck in the air with a piece of flint, or upon a body of inferior magnetic quality, will have its magnetism diminished.

MAGNETISM, ANIMAL, a pretended mode of curing all kinds of disease by means of a sympathetic affection between the sick person and the operator. Towards the conclusion of the 18th century, this scientific nostrum made a considerable noise in England, but soon fell into dispute. On the continent its life was a little more protracted, but in most places contempt arrested its progress, and oblivion became its grave. In Germany some few persons still affect to treat it with veneration, but its credit is irrecoverably lost, its boasted effects having been clearly traced to excited imagination.

MAGNIFYING, is used to denote the apparent enlargement of an object by means of a convex lens, or some other optical instrument, particularly the microscope. See **LENS**, **MICROSCOPE**, **TELESCOPE**, &c.

MAGNIFYING Glass, is a popular term for any convex glass or lens which has the property of magnifying.

MAGNITUDE, is used to denote the extension of any thing, whether it be in one direction, as a line; in two directions, as a surface; or in three directions, which constitute a body or solid.

Geometrical MAGNITUDES, may be conceived to be generated by motion, as a line by the motion of a point, a surface by the motion of a line, and a solid by the motion of a surface.

Apparent MAGNITUDE of a body, is that which is measured by the angle which that body subtends at the eye; at least, this is what is always to be understood by this expression in the science of optics, though in reality the apparent magnitude depends not only on the visual angle, but also upon the supposed distance of the object we are viewing. The mind judges of the magnitude of distant objects on two principles, viz. with reference to the optic angle, and the distance of the object from the eye, the latter arising out of our experience, which shews that distance diminishes that angle; and therefore, without being aware of the deduction, we always make a certain compensation agreeably to the supposed distance. If we see a man, or any other known object, at a distance, it conveys to our mind the idea of a certain magnitude, which we attribute to it entirely independent of the angle which it subtends; but if the object is unknown, then both the distance and the angle are considered, in forming an idea of its magnitude: it is thus that we sometimes deceive ourselves with regard to the size of an object, if we are mistaken as to its distance; thus, a small bird on the branch of a tree may appear to be a larger bird at a greater distance, or the contrary; thus also a fly imperfectly seen in the corner of window, may have the appearance of a crow flying in the open air; these are optical illusions

which commonly happen, and which most persons accustomed to observation, recollect to have experienced at one time or other. It is on this principle, that some writers have accounted for the different apparent magnitudes of the sun and moon, and the apparent distance of two or more known stars, when seen near the horizon, and when they have a greater angle of elevation. When we see the moon, for example, at a considerable elevation, there being no intervening objects between that luminary and the eye, wherewith to make a comparison of its distance, we intuitively suppose it nearer than when we observe it in the horizon; because there are then numerous objects, many of them at great distances, and the moon being evidently beyond them all, we thence suppose its distance greater than in the former case, and the optic angle being still nearly the same, we attribute to it a greater magnitude in the horizon than in the zenith, because we suppose its distance then to be the greatest: hence also the apparent figure of the heavens, which instead of having the form of a perfect concave hemisphere, the eye being in the centre, it has always the appearance of being considerably flattened in the upper part, or being a segment considerably less than a hemisphere. This however is a subject that has much engaged the attention of astronomers and philosophers, from the earliest period to the present time; and various hypotheses have been advanced to account for it, none of which are perhaps perfectly satisfactory.

MAGNOLIA, the laurel-leaved tulip tree, a genus of plants belonging to the polyandria class. The flower of the magnolia is very magnificent, being a fine white, and of large dimensions. This tree loves a southern aspect, and requires to be well nipped up during the severity of our winter.

MAHOGANY. The *Swietenia Mahagoni*, or mahogany-tree, is a native of the warmest parts of America, and grows also in the islands of Cuba, Jamaica, Hispaniola, and the Bahama islands. This tree grows tall and straight, rising often sixty feet from the spur to the limbs; and is about four feet in diameter. The foliage is a beautiful deep green, and the appearance made by the whole tree very elegant. The flowers are of a reddish or saffron colour, and the fruit of an oval form, about the size of a turkey's egg. Some of them have reached to a size exceeding one hundred feet in height. The mahogany-tree thrives in most soils, but varies in texture and grain according to the nature of the soil. On rocks it is of a smaller size, but very hard and weighty, and of a close grain, and beautifully shaded; while the produce of the low and richer lands is more light and porous, of a paler colour, and open grain; and that of mixed soils holds a medium between both. This wood is generally hard, takes a fine polish, and is found to answer better than any other sort in all kinds of cabinet ware.

MAHOMETANS, believers in the doctrines and divine mission of Mahomet, the celebrated warrior and pseudo-prophet of Arabia. The religion of Mahomet is divided into two general parts, faith and practice. The fundamental article of the Mahometan creed is contained in this one confession: *There is but one God, and Mahomet is his prophet*. Under these two propositions are comprehended six distinct branches, viz. belief in God, in his angels, in his scriptures, in his prophets, in the resurrection and judgment; or in God's absolute decrees, or predestination. They reckon five points relating to practice, viz. prayer with washings, &c. alms, fasting, pilgrimage to Mecca, and circumcision. Mahomet admitted the divine mission of both Moses and of Jesus Christ. Mahometism is a borrowed system, made up for the most part of Judaism and Christianity; and, if it be considered in the most favourable point of view, might possibly be accounted a sort of Christian heresy. Achmet Benabdalla, in his letter to Maurice Prince of Orange, says, "The Lord Jesus Christ is held by us (Mahometans) to be a prophet, and the messenger of God, and our lady, the Virgin Mary his mother, to be blessed of God, holy, who brought him forth, and conceived him miraculously by the almighty power of God."

MAIDEN, in ancient English customs, an instrument for beheading criminals. It was in form of a painter's easel, about ten feet high; at four feet from the bottom was a cross bar, on which the felon laid his head, which was kept down by another placed above. In the inner edges of the frame were grooves: in these were placed a sharp axe, with a vast weight of lead

MALLET, in the armory, a peg, to that peg was fastened a cord, which the executioner cutting, the axe fell, and severed the head from the body. This instrument is said to have been introduced into Scotland by the Regent Morton, who himself was afterwards executed by it. This apparatus is now in possession of the society of Scottish Antiquaries. But there is reason to believe it was known in Scotland prior to the time of Morton coming into power, for they show, in the armory at Aberdeen, the maiden with which Sir John Gordon was executed at the time of Queen Mary, after the defeat and death of his father the earl of Huntly, at Corrichie. In France, criminals were sent to death by the maiden or guillotine, since the word *maiden* is also the name of a machine for beheading men in France.

MALICE, in Law, signifies a corporal wound or hurt, by which a man loses the use of any member.

MALICE, in Law, a wound by which a person loses the use of some member that might have been a defence to him, and this crime is punished by 22 and 23 Charles II., without benefit of clergy, though no such offender shall corrupt the blood, or transmit life to his lands, &c.—*Cutting and Maiming* is also, by a recent statute, felony.

MALIN, an epithet applied to whatever is principal, as opposed to what is inferior or secondary; thus, the main land is distinguished from an island, and the main mast, the main wale, the main keel, and the main hatchway, are in like manner distinguished from the fore and mizzen masts, the channel wale, the false keel, and the fore and after hatchways.

Main Tackle, a large and strong tackle, hooked occasionally on the main pendant, and used for various purposes, particularly in securing the mast, by setting up the rigging, stays, &c. See the article *Pendant*.

MAIN-PRIZE, a writ directed to the sheriff, commanding him to take sureties for a prisoner's appearance. (when the officer is bailable, or when the cause of commitment is not properly bailable "below,") and to set him at large. These sureties are termed *mainprisors*, and they can neither imprison nor surrender their man, as "bail," so called, can, but are barely sureties for his appearance at the day.

MAINTENANCE, in Law, nearly the same as *Barrettry*, being an officious intermeddling in a suit that no way belongs to one, by maintaining or assisting either party with money, or otherwise, to prosecute or defend it. This is an offence against public justice; though a man may with impunity maintain the cause of his relation, kinsman, servant, or poor neighbour, out of charity.

MAIZE, or Indian Corn, is a species of grain much cultivated in America and other countries: the grains are yellow when ripe, fat-shaped, like pressed pease, and grow in a sort of knot round the top of the plant. These plants are sown in March, April, or May, and usually yield two crops a year, at the rate of from 15 to 40 bushels per acre. Maise might, with advantage, be cultivated in England.

MAJESTY, a title given to kings.

MAKING UP, among distillers, the reducing spirits to a certain standard of strength, usually called proof, by the admixture of water, which should be either soft and clear river water, or spring water rendered soft by distillation.

MALACHITE, a mineral, the green carbonate of copper, found frequently crystallized in long slender needles; colour green, specific gravity about 3.6. There are two varieties, the fibrous and the compact; the constituent parts are, copper 58.0; carbonic acid 18.9; oxygen 12.5; water 11.5.

MALACIA, in Medicine, a languishing disorder, incident to pregnant women, in which they long at one time for one kind of food, at another for some other kind of food, which they will eat with extraordinary greediness.

MALACOLITE, a mineral found in the silver mines in Sweden and Norway. It is obtained massive, and crystallized in six-sided prisms. Specific gravity 3.25. It consists of silica 53; lime 23; magnesia 19; alumina 3; oxide of iron, &c. 4.

MALACOPTERYGEOUS, in Ichthyology, an appellation given to fishes having the rays of their fins bony at the extremities, but not pointed, like those of acanthopterygous fishes, or thorn-backs.

MALATES, in Chemistry, salts formed by the union of the malic acid with different bases. The malates of potash, soda, ammonia, lime, and barytes, may be formed by dissolving these alkalies in malic acid, and evaporating the solution.

MALE, among zoologists, that sex of animals which has the part of generation without the body. The term male has also been applied to several inanimate things: thus we say a male-flower, a male-screw, &c.

MALIC ACID, is found in the juices of a great many fruits, and it derives its name from its being obtained in great abundance from apples: it is composed of oxygen, hydrogen, and carbon.

MALICE, in Ethics and Law, a design formed for doing mischief to another. In murder, it is malice that constitutes the crime: termed, in an indictment for murder, *malitia pre-cogitata*, or *malice prepense*.

MALLEABLE, a property of metals, whereby they are capable of being extended under the hammer.

MALLET, a wooden hammer, used by artificers who work with a chisel, as sculptors, masons, and stone-cutters, whose mallets are commonly round; and by joiners, carpenters, &c. who work with square-headed mallets.

MALT, a term applied to grain which has been made to germinate artificially to a certain extent, after which the process is stopped by the application of heat. See *KILN*.

The brightness of malt liquor depends much on the accuracy with which the yeast produced by fermentation is separated; and the usual method of effecting this is the following:—The wort, after being duly boiled with the proper quantity of hops, is transferred into coolers, and when its temperature has thereby been sufficiently lowered, it is removed to a large vessel, called the gyle-tun, either open or fitted with a moveable cover. Here, after being mixed with yeast, it undergoes the first fermentation. The half-fermented liquor is then put into barrels lying on their sides, with the bung-hole uppermost, out of which the yeast is continually discharging itself, till the fermentation has ceased or nearly so. During this time the barrels are examined once, twice, or oftener in the day, and are filled up with fresh liquor in proportion as the yeast works off, so that the barrels shall be always full, in order that the yeast, as soon as it rises to the surface of the liquor, shall flow off entirely.

If the whole of the fermentation were conducted in the barrel in which the beer is stored, and at the same time a method was adopted for the escape of the yeast without the constant attention and expense of filling up, as commonly practised, we should then place the barrels upright, and having filled them with the wort previously boiled and cooled, and mixed with the proper quantity of yeast, adapt to each barrel the following apparatus:

This apparatus consists of a tub *c c*, about the size of a peck measure, with a wooden cover *e e*, and having a vertical open pipe of pewter *b*, passing through the bottom; this pipe rises nearly to the top of the tub, and, almost as soon as it has passed through the bottom, expands into a broad flat margin, in order that it may be placed securely over the bung-hole of the barrel *a a*, with paper packing if required. Into the tub is put liquor of the same kind as that with which the barrel is filled, except that it is not previously mixed with yeast; the quantity of the liquor (about one-twelfth) is such as will be rather more

than sufficient to supply the loss in the barrel in consequence of the fermentation. As soon as this process begins, the yeast, rising to the surface of the liquor in the barrel, passes through the bung-hole into the pewter-pipe, and flows out of the upper end of it into the tub, the lighter particles in the state of froth floating on the surface of the liquor, and the heavier ones subsiding to the bottom. The vacuity occasioned by the separation of the yeast is continually supplied from the clear liquor in the tub, which flows in through the lateral hole *d*, in the vertical pipe.

By the adoption of the above described apparatus, we may save about one and a half per cent. in quantity, and have the quality of the liquor also considerably improved, besides avoiding the use of the gyle-tun, and the expense and loss of transferring the liquor therefrom to the barrels, and the loss of liquor in filling up according to the usual mode.

MALT Liquor. *Madame Gervais's Improved Brewing Apparatus.*—Presuming that the attention of the intelligent part of the public may be directed to the subject of brewing, by the notice of a new method of conducting part of that process, which appeared in several periodical publications, it becomes in some measure necessary to elucidate it. This cannot be effected better than by Dr. Birkbeck's judicious abridgment of the pamphlet describing Madame Gervais's improved brewing apparatus.

"I shall not at present," says Dr. Birkbeck, "advert to the conversion of barley into malt, or the artificial formation of saccharine matter by incipient vegetation, but shall begin with the infusion or decoction; that is to say, with the fluid obtained by immersing the bruised malt in hot water, or by exposing it to the action of that fluid when in a state of ebullition. It is next the object of the brewer to convert this fluid, holding mucilaginous and saccharine matter in solution, into wine, in the same manner as the *must*, or expressed juice of the grape, is rendered vinous. The curious process of fermentation is accordingly instituted, by adding a little yeast or ferment, by elevating the temperature, and by slight motion with free exposure to the atmosphere. But before the fluid to be fermented is supposed to be complete, so contradictory often are our opinions and practice, the *hop* must be added, that particular ingredient by which fermentation is to be arrested, or at least the subsequent formation of acetic acid be prevented. And although one practical brewer has shown, more than twenty years ago, that much of the virtue, or, chemically speaking, of the essential oil, of the *hop*, is dissipated by heat, and I have pointed out to several persons engaged in brewing, the inconsistency of adding the *hop* before the first stage of fermentation is finished, yet little has been done in the way of improvement in these respects. To discover when the first stage of fermentation, the *risour*, is complete, much attention is required: of the various methods proposed for determining the point, not one can be pronounced to be either sufficiently accurate or sufficiently easy of application; and accordingly it does happen, both in making beer and wine, that before they are enclosed in casks or bottles, so as to put an end to any further change, vinegar has begun to be formed; or the *alcohol*, the first product, has become converted into *acetic acid*, the second, and the article been rendered unfit for the end first intended. In reference to this difficulty, the new method of managing the fermentation possesses very great advantages. Requiring less heat at the commencement, and liberating less caloric in its progress, on account of the limited supply of oxygen gas, or, rather, being left without any oxygen excepting what itself contains, fermentation will go on more slowly, and must be restricted to a certain point; so that it will become exceedingly difficult to produce any acetic acid. Besides, as the whole of the carbonic acid gas which is generated, must pass through the tube proceeding from the side of the cone, and the water, four inches in depth, in which it terminates, the cessation of the escape of air bubbles, which will be easily noticed, will mark unequivocally the conclusion of the fermentative change. Thus a greater quantity of alcohol will be formed, because, without any risk, the fermentation may be permitted to become complete, in the liquid wherein it occurs. Such part of the spirit *too*, as might fly off during the progress of this spontaneous internal change, will be condensed in the conical cover, kept cool by the water which surrounds it, and will be returned through the small pipe to the fluid below, together with the oily particles

from the *hop*, evaporating and condensed in the same manner, provided the practice should still be continued, of introducing this ingredient before the fermentation is concluded. It will at once appear obvious that this plan is equally applicable to the manufacturing of wines, and has indeed, I understand, been employed successfully by Messrs. Bishops and Harrington, eminent British wine makers in the neighbourhood of Finsbury square. It will be not less obvious likewise, that the improvements now described are fitted for the service of the private brewer and wine maker, not less than for the very extensive manufactories, because to small vats, backs, or fermenting vessels, the conical cap, (with the air-tight condition of the apparatus,) can be applied most effectually. To distillers, this arrangement may become peculiarly serviceable, as it will enable them to allow fermentation to continue in the *wash*, as it is termed, which they prepare, without any danger of its becoming sour, to an extent, and with a degree of perfection as to the quantity of alcohol produced, which they might not otherwise be enabled to accomplish."

The pamphlet commences with the following appropriate and judicious remarks on the subject of vinous fermentation, and proceeds to describe the patent apparatus, and expatiate on its merits with candour and impartiality, as will be seen by the extracts we have made, for the purpose of communicating to the public, a clear and explicit description of the process.

"There is scarcely a single production of the earth, which, when appropriated to the use of man, is not so modified or changed by various preparations, as to possess a different property from that it contained in its primitive state. Fruit and grain undergo decomposition, and a new recombination, before he uses them as food; and until he applied art to the juice of the grapes, they were suffered to decay on the vines—but which the ingenuity of man converted into a pleasant, wholesome, and lasting beverage. In those climates where the only substitutes for wine were milk or water, the inhabitants are indebted to his invention for malt liquor, a beverage, which, although inferior to wine, is not destitute of some of those qualities that render it so great a desideratum.

"The phenomena by which these new properties are produced, is termed the vinous fermentation; it might, perhaps with more propriety, be called the alcoholic or spirituous fermentation, since it is a process by means of which all saccharine matters, whether they proceed from grapes, sugar-cane, or malt, are decomposed, and recombine to form alcohol. But however wrong this denomination may be, we shall make use of it in the following observations, as being well understood by all classes. A vinous fermentation, to be perfect, requires very exact proportions of mucilage and saccharine matter, so as to have the one just sufficient to destroy or attenuate the other; in which case the result would be, if the operation had been properly conducted, a mixture of alcohol and water, differently flavoured, according to the materials from which it was produced, as grapes, pears, apples, or malt and hops; but such accuracy in the proportions cannot be expected either from nature working at large, and every climate, soil, and situation, or from short-sighted man acting mechanically, and frequently in ignorance of what he is doing. A perfect fermentation, therefore, has been considered an object almost impossible to be obtained; and all we wish to shew is, that the errors of the mixture may be corrected; and the whole process improved, by good management.

"The common practice, until a few years back, has been to ferment in open vessels; and though it was a circumstance well known among chemists, that a certain portion of spirit and flavour escaped in the form of vapour during the process, yet no one had an idea that the condensatory system could be applied; as it appeared impossible to effect the fermentation in air-tight vessels, being unable to surmount the great difficulty which existed of keeping down and managing that enormous bulk of non-condensable gases, which are emitted during the decomposition of the saccharine matter, and which acquire greater expansive force by the gradual increase of heat. The idea, however, occurred to Madame Gervais, a proprietor of considerable vineyards near Montpellier, who has founded a system on the following principle; that what is termed the vinous fermentation is a mild, calm, and natural distillation; which, according to the usual acceptance of the word, has proved a cor-

rect system, since not a single drop of spirit is formed before it commences, nor after it is over. Having first laid down this ground-work, she proceeded to obtain an apparatus, that would operate in such a manner as to return into the vessel the spirit and flavour that was evolved from the fermenting gyle, and let out the non-condensable gases which might, by the increasing heat, acquire too great an expansive force, and burst the working tun; a short description of this apparatus will be a fresh proof that the greatest advantages are often derived from the most simple means. It consists of a vessel resembling the head of the ancient still, and constructed of such form as to be capable of being placed securely on the back or vat, in which the process of fermentation is to be carried on; the back or vat must be closed air-tight, with a hole in the top, communicating with that part of the apparatus called the cone or condenser. This cone is surrounded by a cylinder or reservoir, which is to be filled with cold water, so that the alcoholic vapour or steam evolved during the process, may be condensed as it comes in contact with the cold interior surface of the cone; and being thereby converted into liquid, trickles down the inside of the condenser, and through a long pipe is returned into the fermenting liquor.*

"By the application of this apparatus, a considerable portion of alcohol, which has been hitherto suffered to escape in the form of vapour, along with the non-condensable gases, is condensed, and returned into the liquor; and the non-condensable gases are carried off by a pipe, which, proceeding from the interior lower part of the cone, and running up to the inside of the cylinder in the cold water, passes out through the side, and the end is immersed some depth below the surface of water contained in a separate vessel, permitting the gases to escape, but still under a certain degree of pressure, the object of which is, to confine the alcoholic steam and gas within the cone, and allow them a sufficient time to cool and condense."

References to the Engraving.—A A, closed vat in which the process of fermentation is carried on. B condensing cone,

communicating immediately with the interior of the fermenting vat. C C, small channel extending round the interior base of the cone, for the purpose of receiving the condensed alcohol and essential oils, which are conducted down the small tube D into the vat. E E, reservoir for containing cold water surrounding the cone. F, exit-pipe communicating with the interior of the cone, its extremity being immersed some inches below the surface of the water in the small tub G, from which the non-condensable gases are permitted to escape into the atmosphere. H, cock to draw off the water from the reservoir, E E.

"To persons in the least acquainted with chemical operations, it would be useless to dwell on the merits of this apparatus; they will at once see how beneficial it would prove to any liquid that has to undergo the vinous fermentation in any stage of its manufacture; but to those who are not so conversant in the principles and causes of these operations, we shall proceed to point them out.

"To obtain a good fermentation, as complete a decomposition of the must or wort, and as perfect a recombination of alcohol as possible, are the great objects to be obtained. To acquire the former, three requisites are necessary; fluidity, heat, and motion: the latter, density, coolness, and tranquillity. Let us examine each of them separately: first, of fluidity. The specific gravity of the liquid most eligible to produce a good fermentation, is between 1.020, and 1.140; or eighteen for one hundred and thirty-two pounds, by Dica's improved saccharometer made by Joseph Long, No. 20, Little Tower-street, London. Below eighteen pounds of real extract per barrel, the liquid is too thin to produce a proper fermentation, and above one hundred and thirty-two pounds it is too thick; but supposing the specific gravity of the must or wort to be correct, it may be carried beyond a proper dilution by too much heat, or congealed to too great a consistency by excessive cold; consequently, either a thunder storm or hard frost will derange the operation, and are equally injurious to fermentation. Any method therefore that will ensure an even temperature, must be of great importance: and such a method is obtained by applying the apparatus already described, since, by preventing the access of atmospheric air, the sudden changes of the external temperature can have no effect upon the fermenting gyle: and if it has been pitched at a proper heat, (which is between sixty-five and eighty,*) will proceed through its different stages as well during the hottest days of summer, as in the selected months of autumn and spring.

"With respect to motion, we are indebted to Monsieur Gay Lussac, an able French chemist, for a beautiful and important experiment, proving that must, possessed of all the requisites to produce a good fermentation, will not begin to ferment unless excited by a foreign agent. He placed the must in a close vessel, from which the atmospheric air had been exhausted, where it remained several days without giving any signs of fermentation, from which he concluded some power was wanting to break the union of its constituent principles; he therefore introduced a small quantity of oxygen, which immediately caused the must to ferment, evidently proving the necessity of a small portion of atmospheric air, (which contains oxygen,) to allow the fermentation to commence. But it at the same time proves, that, after performing that office, this great enemy to all fermented liquors may be dispensed with, without impeding the process; as the small quantity of oxygen introduced by Monsieur Gay Lussac, was soon absorbed by the carbon to form carbonic acid gas, and he found no occasion for any further supply.

"This discovery is of the greatest importance, since it enables us, without the least detriment or inconvenience to the process, to exclude the oxygen of the atmospheric air, which by constantly supplying the gyle with the principle that causes and promotes acidity, casts on it from the first that roughness and disagreeable flavour which spoil most of our common beverages. Here again the new apparatus proves of infinite benefit; for as soon as carbonic acid gas is evolved from the fermenting gyle, the atmospheric air being lighter, is driven out from the upper part of the working-tun, and as no air is per-

* Fermentation will take place from forty-eight to one hundred and thirty-eight degrees.

mitted to enter afterwards, all the subsequent carbonic acid gas emitted diminishes the quantity of oxygen contained in the gyle by the oxygen uniting with the carbon as fast as it dissolves from the saccharine matter during its decomposition, and thereby secures a soundness and peculiar mildness not to be procured by any other mode.

"Having stated the necessary conditions for a complete decomposition of the saccharine matter, we shall proceed to notice those required for a good production of alcohol. The first already mentioned is a certain density, in order to allow the several principles which are disunited to recombine. It is doubtful whether such a combination will in any case take place, until the temperature of the gyle having attained its greatest heat, is afterwards cooled a few degrees: a fact confirming which is, that a portion of the liquid taken out when at its greatest heat, and tried by distillation, produced little or no spirit; but such refrigeration must not be effected too suddenly, as it might coagulate the yet undecomposed mucilage, and check its further action on the remaining saccharine matter; and by arresting that natural operation, which ought to be pursued a longer or shorter period according to the specific gravity of the fermentable matter, might produce that result termed *ropiness*, by holding in solution the coagulated mucilage.

"Here again the apparatus will be found of great service; for by frequently renewing the cold water in its reservoir, the external temperature will gradually diminish by the heat of the gyle coming in contact with the cold interior of the cone; but in order to effect this, the tranquillity above mentioned is necessary, since the continual motion is caused by the oxygen soliciting new combinations with the carbon, and thereby constantly giving rise to a fresh supply of heat.

The writer then replies very satisfactorily to some objections which have been urged against the adoption of the patent apparatus, and shows it applicable, not only to the process of brewing malt liquors, but to the manufacture of wine, cider, perry, and vinegar. We shall now conclude with the following observations: The great advantages to be derived from this system are, excluding the atmospheric air, by which the acid principle which beer absorbs from the air during fermentation, is prevented entering into combination with it, and thereby insuring the brewer the certainty of making as sound beer during the hot weather as in winter: also the essential oil of the hops and the spirit, which escape on the old principle, are condensed, and returned immediately into the beer, thereby preserving an uniform flavour at all times. In addition to the preservation of flavour, strength, and soundness, and enabling the brewer to insure his beer, an increase of five per cent. is gained in the quantity, not only by condensing the alcoholic vapour, but by the yeast settling in a solid body, at the bottom of the tun, so that the beer may be drawn off clear to the last, and the yeast will be left in good condition for pitching with; likewise, the waste occasioned by the old system of cleansing will be prevented, and the beer will retain the fixed air in it, according to the resistance placed at the end of the escape-pipe, and a considerable saving of labour attend it.

Upon the new system, the fermentation may be brought to a perfect state at any period, according to the degree of heat made use of for fermentation; for as long as there remain any particles of saccharine matter in solution undecomposed, so long will the beer continue to increase in strength, arising from the decomposition of these particles, and which can only be promoted by their dilatation with a high fermentation heat; but when the whole of the saccharine matter is decomposed, and as perfect a fermentation as possible obtained, attenuation will be complete, and the beer will precipitate perfectly bright, there being no longer any carbonic acid gas generated to stir up the grosser particles of the fermented matter. Upon the old system of fermentation, beer can seldom be kept until it has attained a perfect state of attenuation; for as the decomposed particles of saccharine matter yield the basis of spirit, so also they yield the basis of acidity; and the beer having already absorbed too large a portion of that principle, an increase of attenuation is generally accompanied with a great increase of acidity. The flavour of beer, on the old system, depends upon the fermentation-heat, as the greater the heat in the tun, the

larger is the quantity of essential oil evaporated, with a consequent loss of flavour; therefore to insure a good flavour, a low fermentation is necessary, and the lower the fermentation, the longer the saccharine matter is before it decomposes; whereas, on the new system, the whole flavour and strength are preserved, and any degree of heat may be employed to accelerate the fermentation, and bring the beer to an early attenuation.

MALT Distillery, the converting fermented liquors into a clear inflammable spirit, which is either sold for use in the common state of a proof strength, or rectified into spirits of wine, or made into compound cordial waters.

MALTA, KNIGHTS OF, or HOSPITALERS of St. John of Jerusalem, a religious military order, whose residence was in the island of Malta. The order consisted of three estates, the knights, chaplains, and servants at arms. The government of the order was partly monarchical and partly aristocratical: the grand master being sovereign, none were admitted into this order but such as were of noble birth.

MALTHA, in Antiquity, a cement of which there were two sorts, native and factitious: one of the latter consisted of pitch, wax, plaster, and grease. Another kind, used by the Romans in their aqueducts, was made of lime slacked in wine, incorporated with melted pitch, and fresh figs. Native maltha, called also sea-wax, is a solid substance, found on the lake Baikal, in Siberia. It is white, melts when heated, and, on cooling, assumes the consistence of white cerate. It has also been found on the coast of Finland.

MAMALUKES, the line of a dynasty that reigned in Egypt. The Mamalukes were originally Turkish and Circassian slaves, bought of the Tartars by Meliesalah, to the number of a thousand, whom he bred up to arms, and raised some to the principal offices of the empire. They killed Sultan Moadam, whom they succeeded. The mamalukes were skilful horsemen. Their numbers were kept up by the purchase of fresh slaves, and so they continued for many centuries, ruling Egypt in the name of the Grand Signior of Turkey, until the conquest of Egypt by Buonaparte. They then retreated into Nubia, and in 1811 they were decoyed into the power of the Turkish pacha, and slain.

MAMMA, from *Mamma*, the fond word for Mother. This word is said to be found for the compellation (word of salutation) of Mother, in most languages, and is therefore supposed to be the first syllables that a child pronounces.

MAMMALIA, is properly a branch of Natural History, and indicates the first class of the animal kingdom, containing those animals which suckle their young. Several scientific and ingenious arrangements of the animal kingdom into classes, orders, genera, and species, have been successively adopted; that of Monsieur Cuvier, the French anatomist, possesses a high degree of merit. But though his arrangement evinces great anatomical precision, and the highest philosophical knowledge of animals, yet, to a general reader, it has a complicated and forbidding appearance, and is less attractive than the more simple arrangement of *Linnaeus*, which divides the animal kingdom into six classes; *mammalia*, *aves*, *amphibia*, *pisces*, *insecta*, *vermes*: or, such as suckle their young; birds; creatures living equally on land or in the water; fishes; insects; and worms. Each of these classes is subdivided into orders, genera, species, and varieties of those species. These classes are thus arranged for conciseness:

CLASSES.		
Body.	Hot blood —	Viviparous . . . 1. Mammalia.
	With vertebræ . . .	Oviparous . . . 2. Birds.
	Cold red blood . .	With lungs . . . 3. Amphibia.
	Without vertebræ . .	With gills . . . 4. Fishes.
	Cold white blood	Have antennæ . . 5. Insects.
		Have tentacula . 6. Worms.

The class *mammalia*, consists of such animals as produce living offspring, and nourish their young with milk supplied from their own bodies; it comprises both the quadrupeds and whales. Their head is the seat of the principal organs of sense, the mouth, the nose, the eyes, and ears.

Touching or feeling. The outside of the skin is covered with a thin pellicle, called the *epidermis*, cuticle, or scarf-skin. Under the cuticle, is the *rete mucosum*. In negroes, this substance is black; in Europeans, white, brown, or yellow. The *cutis vera*, or the skin, is a substance made up of fibres closely connected

with each other, and running in various directions, being composed of the extremities of numerous vessels and nerves. The *papillæ* of the fingers or inside of the hand, may become erect or elevated, and being gently pressed against a tangible body, receive an impression which is conveyed to the brain, and is called *touch*. Spiders, flies, and ants, have this sense in the greatest perfection.

Tasting. The tongue is covered with two membranes; the external is thick and rugged, especially in quadrupeds; the internal membrane is thin and soft, and upon it appear *papillæ*, or small elevations, like the tops of the small horns of snails. These *papillæ* are composed of the extremities of the nerves of the tongue, and piercing the external membrane, are constantly affected by those qualities in bodies, which have their tastes excited in the mind by means of these nervous *papillæ*, which are the immediate organ of tasting. This organ bears a strong analogy to the sense of touch.

Hearing. The undulations of the atmosphere, excited by the vibrations of sonorous bodies, are collected in the external ear and auditory passage, as in the hearing trumpet, and are conveyed to the *membrana tympani*, or drum, which they cause to vibrate. The effect is transmitted through the small bones, to the watery fluid that fills the internal ear, in which the delicate filaments of the auditory nerve float, and by this nerve the sensation is conveyed to the brain. But it is remarkable how nicely is the ear constructed in various animals; in man its position and form are admirably contrived for his erect posture; in quadrupeds we see it large, susceptible of easy motion, as when the horse lays his ears back or points them forward; in the mole it is lodged deep in the head. The structure of the ear is also remarkable, for it is so contrived and tunnelled that it may not only catch sounds, but prevent the more furious undulations of the air from injuring the interior membrane. And to prevent insects from lodging within its cavity, as well as to keep it moist and in tune, it is supplied with a bitter nauseous wax.

Smelling. The cavity of the nose is divided into two parts, called the *nostrils*, by a partition, of which the upper part is bony, and the lower cartilaginous. The upper part of the cavity is covered with a thick glandulous membrane, above which the *olfactory nerve* is finely branched out and spread over the membrane of the spongy bones of the nose, and other sinuous cavities of the nostrils. The odorous effluvia of bodies being disseminated in the atmosphere, the latter fluid passes through the nose in respiration, and the odorous particles are thus brought into contact with the fibres of the nerves, which, by their communication with the brain, excite in the mind the sense of smell.

Seeing. The eye is the organ of sight, and its sensations are of the utmost importance to the well-being and safety of animals. The eye is composed of three coats, covering one another, and enclosing different substances called *humours*. The three coats are the *scleroticæ*, the *choroides*, and the *retina*. The three humours are the *aqueous*, the *crystalline*, and the *vitreous*. Objects are seen by means of their images being painted on the retina of the eye, in an inverted position, though they appear erect. When the crystalline humour loses its transparency, the disorder is called a *cataract*, and the remedy applied is called *couching*, which is performed by thrusting a fine awl through the coats of the eye, and pushing the crystalline to the bottom of the eye, where it will remain, and its deficiency may be supplied with a convex lens. When the defect of vision is in the optic nerve, it is called a *gutta serena*, and the disorder is generally incurable. The external parts of the eye are, the eye-brows, the eye-lids, and eye-lashes. The eye-brows defend the eyes from too strong a light, and serve to turn away substances which might otherwise fall into the eye. The eye-lids act as curtains, by covering and protecting the eyes during sleep; and in our waking hours they diffuse a fluid over the eye which renders it better adapted to transmit the rays of light. The eye-lashes guard the organ from danger, and protect it from dust and insects floating or flying in the atmosphere.

The mouth contains the teeth, which are inserted into two moveable bones, the upper and under jaw. The front or cutting teeth are in general wedge-shaped, and so placed that in action their sharp edges are brought into contact. Next to

these are situated the canine teeth or tusks, which are in general longer than the front teeth; conical; and pointed. The teeth in the back of the jaw, and between which the food is chewed or masticated, are called grinders. In such animals as subsist on vegetable food, the latter are somewhat flattened at the top; but in the carnivorous tribes, their upper surfaces are furnished with sharp and conically pointed protuberances. It is principally from the numbers, form, and disposition of the teeth, that Linnæus has arranged the various genera or tribes of quadrupeds.

The class Mammalia has been distributed into seven orders, founded for the most part on the number and arrangement of the teeth; and on the form and construction of the feet, or of those parts in the seals, whales, and other animals, which supply the place of feet.

Orders of Mammalia.—1. Primates, have the upper front teeth generally four in number, wedge-shaped, and parallel; and two teats situated on the breast, as apes and monkeys. 2. Bruta, have no front teeth in either jaw; and the feet armed with strong hoof-like nails, as the elephant. 3. Fera, have in general six front teeth in each jaw; a single canine tooth on each side in both jaws; and the grinders with conic projections, as the dogs and cats. 4. Glires, have two long projecting front teeth in each jaw, which stand close together; and no canine teeth in either jaw, as the rats and mice. 5. Pecora, have no front teeth in the upper jaw; six or eight in the lower jaw, situated at a considerable distance from the grinders; and the feet with hoofs, as the cattle and sheep. 6. Belluæ, have blunt wedge-shaped front teeth in both jaws; and the feet with hoofs, as the horses. 7. Cetæ, have spiracles, or breathing holes, on the head; fins instead of fore feet; and a tail flattened horizontally, instead of hind feet. This order consists of the narwhals, whales, cachalots, and dolphins.

MAMMARY GLAND. In Anatomy, is a glandular substance situated in the breast, and secreting the milk.

MAN. The varieties of the human species, as arranged by Blumenbach, are five in number:—1. Caucasian variety, which includes the Europeans, (excepting the Laplanders, and the rest of the Finnish race,) the western Asiatics, as far as the river Ob, the Caspian sea, and the Ganges, and the northern Africans. 2. Mongolian variety, which includes the rest of the Asiatics, (excepting the Malays;) the Finnish races of the colder parts of Europe, as the Laplanders, &c. and the tribes of Esquimaux; extending over the northern parts of America from Bhering's Strait to the extremity of Greenland. 3. Ethiopian variety, contains the remaining Africans, besides those classed in the first variety. 4. American variety. To this belong all the Americans, except the Esquimaux. 5. Malay variety, includes the inhabitants of Malacca, of the South Sea, Ladrone, Philippine, Molucca, and Sunda islands. Each variety is distinguished by the colour of the hair, and some striking peculiarities of feature. We shall now briefly describe the external and internal structure of the human body, and the five senses.

External Structure of the Human Body.—Among all the visible parts of the body, the head holds the most distinguished place; both because of its beauty, and because it contains the principles of sense and motion. All the sentiments and passions of the soul are painted on the face, which is the most beautiful part of man; and where the principal organs of sense are found, through the medium of which we receive impressions from external objects. The different motions of the lips, and those of the tongue, whether it touch the palate or the teeth, serve for the articulation of words, and the different inflexions of sound. By the teeth we can cut or grind our food; and the saliva, so necessary to digestion, is furnished by a great number of glands, which are contained in the mouth. The head is placed upon the neck, and turns as on a pivot, to any side we please. After the neck comes the shoulders, so formed that they are able to bear heavy loads. To the shoulders the arms are joined; and to those, the hands, which are so constructed as to perform an infinity of motions; to touch, take, raise up, draw back, repel, &c. the joints and bones serving to support and facilitate these motions. The breast includes and defends the heart and the lungs; and for this purpose it is composed of strong and hard ribs and bones. The diaphragm

separates the breast and belly, which contains the stomach, liver, spleen, and intestines. All this mass rests upon the hips, thighs, and legs, which, like the arms, have different articulations favourable to motion and rest. The feet sustain the whole, and the toes also contribute to it, because they serve to fix the feet more firmly upon the ground. The skin and flesh cover the whole body. The hair and the down, which are found in different parts, protect them from the injurious effects of cold. The bones, the most compact and solid parts of the body, serve for the attachment and support of all other parts. Bones are firm, hard, and perfectly insensible, they are divided into the long, the cylindrical, and the flat. There are 248 separate bones in the human body; these, connected with wires, are sometimes made up into an artificial skeleton. There are eight separate bones in the skull, that serves as a vault for the brain. The vertebrae of the neck, so called from the ease with which they move, are separated from one another by an elastic substance. They support the head, which by their means is readily moved up and down, and turned round on either side as far as is necessary, like a piece of mechanism in a ball and socket; to the breast bone, the seven true and five false ribs are fastened; the spine extends from the skull to the end of the loins, and serves to lodge and defend the spinal marrow; the pelvis supports the abdomen, and the thorax reaches from the neck to the end of the breast bone, serving as a chest or place of safety for the heart, lungs, &c.

The Muscles, Arteries, Veins, and Circulation of the Blood.—The muscles constituting the flesh are susceptible of contraction and relaxation, and, with the help of the tendons, are the instruments of animal motion. The muscles are either *voluntary* or *involuntary*. The motions of the former are subject to the will, as in the case of the arms, legs, &c. The heart, which is a hollow muscle, and the stomach, intestines, &c. act upon their contents by means of muscular fibres, called involuntary muscles, because their motions depend not on the will. Each large muscle consists of two parts, viz. the belly, which is the active part, and its cord-like extremities called tendons, which fasten the muscle to the bones, and perform their action by contracting both ends towards the centre. The red colour which distinguishes the muscular parts of animals is owing to the number of blood-vessels dispersed through their substance. The nerves, long, white, medullary cords, originate in the brain and spinal marrow, and serve for sensation. *Sensibility*, therefore, depends on the nerves; *motion*, on the muscles. The nerves conduce to all the enjoyments and sufferings of life, and to the intellectual faculties of man: the muscles are the chief support of animal life, and the source of all the bodily powers. The heart is the principal organ of life; it contains four cavities for receiving the blood, and giving it a fresh impulse through the arteries. The arteries originate in the heart, and through them the blood is carried from the heart to every part of the body, for the preservation of life, generation of heat, nutrition, and the secretion of the different fluids. The pulse, felt at the wrist, temples, and various parts of the body, is occasioned by the reciprocal action of the heart and arteries, when the blood is driven from the heart into the arteries to be distributed through the whole body. The arteries terminate in small microscopic veins, which bring back the blood from the extremities to the heart. The veins originate at the extremities of the arteries; they continually increase in size as they approach the heart: they do not pulsate, but the blood they receive from the arteries, they carry back with a slow motion, and it is prevented from returning by innumerable valves. The double circulation of the blood is this: one motion is from the heart to the lungs, for the purpose of receiving oxygen from the air; the other motion is over all the parts of the body, to give out its nutritive and vital properties to the whole machine.

The Brain and Nerves.—The brain, a small pulpy mass of a whitish colour, occupies all that cavity formed by the bones of the skull. The spinal marrow, a continuation of the brain, passes out of an opening in the skull, and runs down the canal of the back-bone, giving out nerves in its passage. The nerves run out in pairs, separate and spread over the whole body. The brain and nerves constitute entire the organs of feeling and sensation, the other parts of the body being incapable of feel-

ing. Excitement to action, produced by the will, proceeds from the brain and spinal marrow, through the medium of the nerves. The nerves are therefore the organs, the brain the receptacle, of all our sensations, and the source of all our ideas.

The Stomach, Liver, Digestion, &c.—The stomach, shaped like a bag, is the grand receptacle for the food, where it is retained until it is changed by *digestion*. The stomach has two openings, one called the *œsophagus*, through which the food passes into it; the other, intended to carry away the digested substance, is called the intestinal canal. The chief agent in digestion is the *gastric juice*; by the muscular nature of the stomach, the food when properly digested is propelled through the intestinal canal into the intestine, a membranous tube, about five times the length of the person in which it is contained. Food is called *chyme*, in which state it enters the intestine, where it undergoes another change, and the *chyle*, a milk-like substance, is separated from it. Chyle is that substance from which the blood is formed, it is absorbed by the mouths of the lacteal vessels, every where distributed in the intestines, while the feculent parts of the chyme and the bile are driven into the large intestine, by which it is expelled from the body. The liver is formed for the secretion or separation of the bile from the blood, which passes into the *ductus hepaticus*, and thence into the gall-bladder, where it is kept till it is wanted to mix in the intestine. The chief uses of the bile are, to extricate the chyle from the chyme; and to excite the peristaltic motion of the bowels. The lacteals convey the chyle from the intestine into the jugular vein, that empties itself into the heart. The kidneys are two glandular substances which drain the system of its redundant water; for this purpose a considerable portion of the blood is perpetually passing into each kidney, where it leaves its superfluous water, and then returns into the circulation by means of a particular vein. The water thus strained from the blood is carried by canals into the bladder, into which it passes through its two coats, which answer the purpose of a valve to prevent regurgitation.

MAN. By this word, used in the sea language, a ship is frequently understood as a Man of war, a Merchantman, a Guinea-man, an East Indianman, a Greenlandman, &c. in all which instances the word ship is implied. *To Man*, is to place men sufficient for any particular exercise at the proper station: as, *Man the Captain*, that is, place the men to the bars in readiness to heave. *Man the Top-sail Sheet*, that is, let the men lay hold of, and be ready to pull up, the top-sail sheets. *To Man the Ship*, is to range the people on the yards and rigging, in readiness to give three cheers, as a salute. *To Man the Yards*, to send a sufficient number of men upon the yards to reef or furl the sails. *To Man a Prize*, to send a proper number of men on board to navigate her.

MANCIPLE. (*Manceps*), a clerk of the kitchen, or caterer. An officer in the inner temple was anciently so called, who is now the steward there; of whom Chaucer, the ancient English poet, sometime a student of that house, thus writes:

A manciple there was within the temple,
Of which all caterers might take ensample.

This officer still remains in colleges in the universities.

MANDAMUS. in Law, a writ that issues out of the Court of King's Bench, sent to a corporation, commanding them to admit or restore a person to his office. This writ also lies where justices of the peace refuse to admit a person to take the oaths in order to qualify himself for enjoying any post or office; or where a bishop or archdeacon refuses to grant a probate of a will, to admit an executor to prove it, or to swear a churchwarden, &c.

MANDRAKE. See *ATROPA*.

MANDREL. a kind of wooden pulley, making a member of the turner's lathe. Of these there are several kinds; as, Flat Mandrels, which have three or more little pegs or points near the verge, and are used for turning flat boards on. Pin Mandrels, which have a long wooden shank to fit into a round hole made in the work to be turned. Hollow Mandrels, which are hollow of themselves, and used for turning hollow work. Screw Mandrels, for turning screws, &c.

MANE. the hair hanging down from a horse's neck, which should be long, thin, and fine; and, if frizzled, so much the better.

MANGE, or *Mange*, the contrivance of riding the ground-horse; or the ground set apart for that purpose; which is sometimes covered, for continuing the exercise in bad weather; and sometimes open, in order to give more liberty and freedom both to the horseman and horse. See *HORSEMANSHIP*. The word is borrowed from the French *mange*, and that from the Italian *mangia*; or, as some will have it, a *mange* spread, "eating with the hand."

MANGANESE, a metal which is not only an object of interest in the speculations of the experimental chemist; but of the utmost use in manufactures, from its being employed to furnish the chlorine gas, which is so effectual in bleaching. It is a metal of a dull whitish colour when broken, but which soon grows dark by oxidation from the action of the air. It is hard, brittle, though not pulverisable, and rough in its fracture; so difficultly fusible, that no heat yet exhibited has caused it to run into masses of any considerable magnitude. Its sp. gr. is 6.8. When broken in pieces, it falls into a powder by spontaneous oxidation. Concentrated sulphuric acid attacks manganese, at the same time that hydrogen gas is disengaged. The ore of manganese, which is known in Derbyshire by the name of *black add*, is remarkable for its spontaneous inflammation with oil. It is of a dark brown colour, of a friable earthy appearance, partly in powder, and partly in lumps. If half a pound of this be dried before a fire, and afterwards suffered to cool for about an hour, and it be then loosely mixed or kneaded with two ounces of linseed oil; the whole, in something more than half an hour, becomes gradually hot, and at length bursts into flame. This effect wants explanation. It seems, in some measure, to resemble the inflammation of oils by the nitric acid. Manganese was used chiefly by glass-makers and potters; but the important discovery of chlorine has greatly extended its utility.

MANGROVE, in sea language, a small space extending athwart the deck of a ship of war immediately within the mainmast, and separated on the after-part from the other part of the deck by the manger board, a strong bulk-head, built as high as, and serving to stop the water which sometimes rushes in at the bulwark-holes, and would otherwise run aft in great streams on the deck; the water, thus stopped, is again returned into the sea through the scuppers.

MANGLE, a valuable domestic machine, employed for the purpose of smoothing such linen as cannot be conveniently ironed. Various patents have been granted for improvements in this machine: but, as many of them are too complicated to be understood without very tedious details, we have represented but improved mangle contrived by Mr. Jee, of Rotherham. (See the Plate.)

A, fig. 11, points out the great wheel, which, in machines of a full size, is 15 inches in diameter. B, the arbor, on which the belt, C, is fixed. D, the handle of the winch. E, the crank, 21 inches in length. F, the rod of the crank. G, G, represents the hollow studs, by which the ends of the bed are lifted up. H, H, the levers. I, I, I, the four pulleys fixed on the moveable bed K. L, L, the ends of the rollers. Fig. 12, represents a front view of one of the hollow studs G, to shew its form when standing at the end of the bed; and into which the levers enter sufficiently, as often as it becomes necessary to elevate the bed, in order to put in, or take out, the rollers.

This mangle is so constructed, that the handle requires to be turned but one way only, in consequence of which the machine moves with greater facility, and with incomparably less injury to the linen, than by varying the turnings, and in a manner cutting the different folds. Besides, it possesses the great advantage, that a woman and one boy are sufficient to work it, and can perform as much labour in the same period of time as three or four persons with mangles of the common construction.

Mr. Jee's Patent Mangle, being compact and moderately simple, may here be described. This mangle is constituted of four horizontal rollers, the pivots of which play on suitable supports in a stout wooden frame put together with bed-screws. To avoid circumlocution, we shall denote these four rollers by the letters A, B, C, D. (see the Plate.) The two rollers A and B, whose axes bear on brass or iron, let into the wooden frame, and pushed into by slide; but not so as to touch. C is a

movable roller, about which the linen or cloth to be smoothed is rolled, and is then placed upon the rollers A and B, so as to lie in part between them. The axis of the fourth roller D works in pieces of brass or iron, which slide between two other pieces of metal, so that this roller D admits of elevation and depression, by means of a lever working upon a horizontal shaft (at the top of the frame) and chains of suspension. The pieces of metal in which the axle of the roller D runs have long vertical pieces of iron attached to them, so as to reach below all the rollers; and to hooks at the lower extremities of these irons are hung chains carrying either a rectangular platform loaded with weights, or a rectangular box containing stones or other ponderous matter. In using this machine, the lever is pressed down and fastened by a hook; by this process the roller D, and platform below it, is elevated; then the linen to be smoothed is wrapped about the roller C, which is next laid to rest between the rollers A and B. The lever is then freed from the hook which kept it down, and the action of the ponderous matter on the platform brings the roller D into contact with the roller C: in this state a rotatory motion is applied to all the rollers by means of a winch fixed to the axle of D; and in a short time the pressure of the roller C, against A, B, and D, will give the requisite smoothness to the linen.

The inventor says, this machine will act best with a wheel on the axis of each of the cylinders A and B, and a pinion between them, with a fly-wheel on the axle of the pinion, to which motion being given, all inequalities of pressure will be conquered with great ease. This machine is not confined to mangling only, but may be used with success as a copper-plate-printing press, a letter-copying machine, &c.

An *Improved Mangle*, by *Eliza Peckey*.—In this machine, a regular alternating motion is carried on by a power continued in one direction. The novelty in this mangle is, the contrivance for obtaining the alternate forward and backward motion of the box, and consequently of the rollers, by continually turning the wheel in the same direction. More than one mode of obtaining this object is already before the public, but the simplicity, ingenuity, and efficacy of the arrangement adopted by Mr. Peckey for this purpose, will be apparent from the following description:—

Figure 1 exhibits a plan or view of the upper side of the mangle. Fig. 2 is an end view. Fig. 3 is a side view; the bottom parts of the frame being represented as broken off, so as to reduce it within the plate; but the whole height is seen in fig. 3. The same letters of reference apply to the same parts in each figure. Fig. 4 is a section of a double rack, *a a* and *b b*, together with the plunger blocks or guides *c c*, (which support and guide the rack or axle *d d*) being cut by a plane in the direction of, and perpendicular to, the axis. Fig. 5 is a similar section, shewing the rack in another situation, as will be hereafter described. Fig. 6 is a view of part of the shaft *d d*, shewing the two journals *e e*, which turn and are supported in the plunger blocks, and also the pinion *f* of three teeth, formed in the middle part of the shaft which works into the racks. Fig. 7 is a section of the plunger block, cut in the direction of the dotted line *g g*, fig. 4, and of the pinion *f*, together with a side view of one end of the racks *a a* and *b b*. Figs. 4, 5, 6, and 7, are drawn double the size of the former.

A, &c. is the frame of the mangle, B B the moveable box which contains heavy weights, and C C two rollers, which are all made in a similar way to other mangles.

On the upper side of the frame A A, &c. are fixed head stocks D D, which are fixed and kept perpendicular to each other by an iron bar *k k*; on the upper side of the bar are fixed the plunger blocks *c c*; the upper and lower parts of the plunger blocks have projecting pieces *i i* and *j j*, which support and guide the double rack, see figs. 4 and 5. *a a* and *b b* is the double rack, which is fixed parallel to the box B B, by means of two perpendicular studs *h h*; the studs pass loosely through loops in each end of the racks, so that the rack is at liberty to move up and down, being at the same time prevented from sliding off by the pins *l l*; each end of the rack is supported by two spiral springs *m m* fixed on the upper side of the box: the ends of these springs pass through small holes in the ends of the rack, and tend to support it in a middle situation, such a position as that the pinion *f*, fig. 7, shall be in gear with the

Construction of Maps.

upper bar of the rack. The double rack consists of a flat bar of iron, having teeth formed in the internal part of it, (as shown in figs. 3 and 7,) and also two fins, or ribs, *a* and *c*, fixed to the upper and lower edges of it, and projecting on each side of the rack. The use of these fins is to support the rack in the two situations, as shown in figs. 4 and 6. *d d* is a shaft or axis, which is supported by the head stocks *D D*, and by the plummer blocks *c c*, having a fly-wheel *p* fixed to one end of it, and a winch *q* to the other, by which means the machine is put in motion: in the middle part of the shaft *d d* is the pinion *f*, which works in the teeth of the rack; in figs. 3 and 7, the pinion is represented working in the rack *a a*: now, suppose a rotatory motion be given to the winch, the pinion will cause the rack, together with the box, &c. to move in a longitudinal direction till the end of the rack has arrived at the pinion, when it will be seen, by referring to fig. 7, that the rack cannot pass any further in that direction. By continuing to turn the winch in the same direction as at first, it is evident that the next tooth of the pinion will take into the gap in the end of the rack, and thus cause the rack to slide up the stand *k*, till the fins on each side of the rack are raised above the projecting pieces *i i* and *j j* of the plummer blocks; the next succeeding tooth will act in the first gap of the lower rack *b b*, which will cause the rack, together with the box, &c. to move in the contrary direction till the other end of the rack has arrived at the pinion, when a tooth of the pinion will act in the gap in that end, and cause the rack to slide down the stand *k*, when the next tooth of the pinion will act in the first gap of the upper rack, and cause the rack to move in the direction first mentioned, and by continuing the motion of the winch in the same direction, an alternate motion of the rack box, &c. is effected.

To replace or change the rollers *C C*, one of the arms *r* or *s* must be turned on the joint by which it is fastened to the plummer block in a direction parallel to the side of the rack, as shown at *r* in fig. 1.

The arm forms an inclined plane, as shown at *r*, fig. 3, so that when the end of the box *B B* approaches towards the centre of the frame, the friction roller *t* (one of which is fixed to each end of the box) passes up the arm or inclined plain *r*, and raises the end of the box, so that the roller *C* may be removed. A new species of mangle, on the principle of the parallel ruler, has been invented, and is called the *perpendicular mangle*; but it seems greatly inferior to the last mentioned machine of this name.

MANICHEES, in Church History, a sect of Christian heretics in the third century, the followers of Manes, who taught that there were two principles, or gods, co-eternal and independent on each other; the one the author of all evil, and the other of all good.

MANIFEST, an inventory of the whole cargo of a merchant ship.

MANIFESTO, a public declaration made by a prince in writing, shewing his intentions to begin a war or other enterprise, with the motives that induce him to it, and the reasons on which he founds his rights and pretensions.

MANILLE, in Commerce, a large brass ring in the form of a bracelet, either plain or engraven, flat or round. Manilles are among the commodities which the Europeans carry to the coast of Africa, and exchange with the natives for slaves. These people wear them as ornaments on the small of the leg, and on the thick part of the arm above the elbow. The great men wear manilles of gold and silver; but these are made in the country by the natives themselves.

MANIPULUS, in Roman Antiquity, a body of infantry consisting of 200 men.

MANIS, in Natural History, a genus of mammalia, of the order bruta. These animals resemble the ant-eater, and feed like that creature by protruding their tongues into the nests of various species of insects, and retracting them with inconceivable suddenness, with their prey attached to the tip. There are three species; the chief of which, the long-tailed manis, has a tail more than twice the length of its body, and is often in the whole seen five feet long. Its colour is a dark brown, with a tinge of yellow, and it displays a very brilliant gloss. It is perfectly covered, except on the belly, with large scales resembling the substance of horn. It is a native of India. The short-tailed

manis, much thicker and shorter than the former, is covered with scales still thicker and stronger. It is found in many parts of India and Africa. It moves with great slowness, but on imminent danger of attack, rolls itself up with the compactness of a ball, and does, in this state, the attempts even of some of the larger beasts of prey. It frequents marshy and woody places, and lives almost entirely on insects, particularly on ants.

MANNA. Several vegetables afford manna, but the ash, the larch, and the albagi, afford it in the largest quantities. The ash which affords manna grows naturally in all temperate climates; but Calabria and Sicily are the most natural countries to this tree. The manna flows naturally from this tree, and attaches itself to its sides in the form of white transparent drops, but the extraction of this juice is facilitated by incisions made in the tree during summer. Its smell is strong, and its taste sweetish and slightly nauseous; if exposed on hot coals, it swells up, takes fire, and leaves a light bulky coal. Water totally dissolves it, whether hot or cold. If it be boiled with lime, clarified with white of egg, and concentrated by evaporation, it affords crystals of sugar. Manna affords by distillation, water, acid, oil, and ammonia; its coal affords fixed alkali. This substance forms the basis of many purgative medicines.

MANNER, in Painting, a habitude that a man acquires in the three principal parts of painting, the management of colours, lights, and shadows; which is either good or bad according as the painter has practised more or less after the truth, with judgment and study. But the best painter is he who has no manner at all. The good or bad choice he makes is called *gout*.

MANNERS, the plural noun, has various significations; as, the general way of life, the morals, or the habits, of any person or people; also ceremonious behaviour, or studied civility. See the next article.

Good MANNERS, according to Swift, is the art of making those people easy with whom we converse. Whoever makes the fewest persons uneasy, is the best bred man in the company. As the best law is founded upon reason, so are the best manners. And as some lawyers have introduced unreasonable things into common law; so, likewise, many teachers have introduced absurd things into common good manners.

MANOEUVRE, in a military sense, consists solely in distributing equal motion to every part of a body of troops, to enable the whole to form, or change their position, in the most expeditious and best method, to answer the purposes required of a battalion, brigade, or line of cavalry, artillery, or infantry. It has always been lamented, that men have been brought on service without being informed of the uses of the different manoeuvres they have been practising; and, having no ideas of any thing but the uniformity of the parade, instantly fall into disorder and confusion when they lose the step, or see a deviation from the straight lines they have been accustomed to at exercise. It is a pity to see so much attention given to show, and so little to instruct the troops in what may be of use to them in real service. No manoeuvre should be executed in presence of the enemy, unless protected by some division of the troops.

MANOMETER, an instrument, intended to measure the rarefaction and condensation of elastic fluids in confined circumstances, whether occasioned by variation of temperature or by actual destruction, or generation of portions of elastic fluid. It is sometimes called *manoscope*. Mr. Boyle's *statical barometer* was an instrument of this kind; it consisted of a bubble of thin glass, hermetically sealed, about the size of an orange, which being counterpoised when the air was in a mean state of density, by means of a nice pair of scales, sunk when the atmosphere became lighter, and rose as it grew heavier. This instrument would evidently indicate the changes of density in the atmosphere, but it leaves us uncertain as to the cause, whether it is from the change of its own weight, or of its temperature, or of both. The manometer constructed by Mr. Ramsden, and used by Captain Phipps, in his voyage to the North Pole, was composed of a tube of a small bore, with a ball at the end; the barometer being at 29.7, a small quantity of quicksilver was put into the tube, to take off the communication between the external air, and that confined in the ball, and the part of the tube below this quicksilver. A scale is placed on the side of the tube, which marks the degrees of dila-

will arise from the increase of heat in this state of the weight of the air, and has the same graduation as that of Fahrenheit's thermometer, the point of freezing being marked 32. In this state, therefore, it will show the degrees of heat in the same manner as a thermometer. But if the air becomes lighter, the bubble enclosed in the ball, being less compressed, will dilate itself, and take up a space as much larger as the compressing force is less; therefore the changes arising from the increase of heat will be proportionably larger, and the instrument will show the difference in the density of the air arising from the changes in its weight and heat. Mr Ramsden found, that a heat equal to that of boiling water, increased the magnitude of the air from what it was at the freezing point 32 of the thermometer. Hence it follows, that the ball and part of the tube being the beginning of the scale, is of a magnitude equal to almost 414 degrees of the scale. If the height of both the thermometer and barometer be given, the height of the barometer may be determined also.

MANOR, was a district of ground, held by lords, or great proprietors, who kept in their own hand so much land as was necessary for the use of their families. The other lands they distributed among their tenants. The produce of the manor, being unappropriated, was termed the lord's waste, and served for common of pasture to the lord and his tenants. All manors existing at this day must have existed as early as King Edward I., and must have a court baron.

MANSE, **MANNA**, **MARSA**, or **MANAUM**, in ancient law-books, denotes a house, or habitation, either with or without land. See **HOTEL** and **MANSION**. The word is formed from a *manse*, "abiding;" as being the place of dwelling or residence.

MANSLAUGHTER. See **HOMICIDE**.

MAST, or **MASTEE-TREE**, in Architecture, the lower part of the chimney, or that piece of timber which is laid across the chimney, and sustains the compartments of the chimney-piece.

MAST, or **Mantling**, in Heraldry, that appearance of folding of cloth, flourishing, or drapery, which in any achievement is shown about a coat of arms. See **HERALDRY**.

MASTELLS, in the art of war, a kind of movable parapet, made of planks about three inches thick, nailed one over another, to the height of about six feet, generally eased with tin, and set upon small wheels, so that in a siege they may be drawn before the pioneers, to shelter them from the enemy's small shot.

MASTIS, a genus of insects, of the order homiptera. There are upwards of 400 species, the chief is the *M. oratoria*, or camel cricket, found in the northern parts of Europe, of a beautiful green colour, nearly three inches in length, of a slender shape, and in its general sitting posture, is observed to hold up the fore legs as if in the act of devotion. The insect is of a predaceous disposition, living on smaller insects, which it watches for with great anxiety: it is also very voracious, and when kept with others of its own species in a state of captivity, they will attack each other with the utmost violence till one is destroyed. The conqueror devours his antagonist.

MANUFACTURES may be defined, the arts by which natural productions are brought into the state or form in which they are consumed or used. The principal manufactures are those by which the various articles of clothing are fabricated; as the woollen manufacture, the leather manufacture in part, the cotton manufacture, the linen manufacture, and the silk manufacture; others supply articles of household furniture, as the manufacture of glass, porcelain, earthenware, and of most of the materials in part; the iron manufacture furnishes implements of agriculture, and weapons of war; and the paper manufacture supplies a material for communicating ideas and perpetuating knowledge.

MANURE. See **MANURE**.

MAPLE, *Acer Pseudo-Platanus*. By tapping this tree it yields a liquor not unlike that of the birch tree, from which the Americans make a sugar, and the Highlanders sometimes an agreeable and wholesome wine.

MAPS. A map represents the earth, or only a portion of its surface, as Great Britain. The former are called universals; the latter, particular maps. The upper part of a map is the north, the lower the south, the east is on the right hand side

and the west is towards the left hand; the map is laid before you as it can be viewed. The method of construction is the perpendicular margins of the east and west; the longitudes on the horizontal margins at top and bottom.

The Construction of Maps.—**Prob. I.** To construct a Map of the World on the plane of a meridian 41° by the globular projection of the sphere. (See the Plate, fig. 1.)—The globular projection of the sphere, represents spaces on the surface of the globe by equal spaces of the projected map, as nearly as a spherical surface can be represented on a plane. The plane of projection is the plane of one of the great circles of the sphere passing through both poles, and crossing the equator at right angles. A hemispherical map is a representation of the whole surface of the Earth, projected on the plane of one of its great circles.

To draw the meridians, or circles of longitude.—Draw *AB* and *NS* at right angles to each other, *AB* representing the equator, and *NS* the axis meridian. From *C* as a centre, with any radius, *CA* or *CB*, according to the size of your paper, describe the circle *A N B S*. This circle is then the plane of your projection. Divide the four radii, *CA*, *CN*, *CS*, *CB*, each into nine equal parts.

Now, to draw the meridian 80° west of Greenwich, we have the two poles, and the point 80° in the equator, *A B*. From *N* as a centre, and with *NC* as a radius, describe the arc *N C 1*; also from *S*, with the same radius, describe the arc *S C 2*. Remove the compasses to the point 80 on the equator, and describe the arcs *1*, *1*, and *2*, *2*. Through the intersections *1*, *1*, and *2*, *2*, draw lines from *C*, through the points *1*, *1*, and *2*, *2*, they intersect the diameter *BA* produced in *D*. Then will *CD* be the equator from which, with the radius *NC*, or *CS*, the meridian of 80° west longitude from Greenwich must be described. The same radius will draw the meridian expressing 140° W. L.; and on the other hemisphere, the corresponding meridians of east longitude.

The meridian of 50° is drawn in the same manner as that of 80°, except that the point 50 on the equator (*A B*) is the centre from which, with the radius *CB*, the intersections are made at *a, a*, and *b, b*, on the arcs described from *N* and *S*. The point *E*, where the lines *a, a*, *b, b*, meet on the equator, is the centre for the meridian of 50° W. longitude. The same radius serves for the other three meridians 30° within the circle of projection. In this manner are all the other meridians for both hemispheres to be drawn; as may be seen in the Plate, fig. 7.

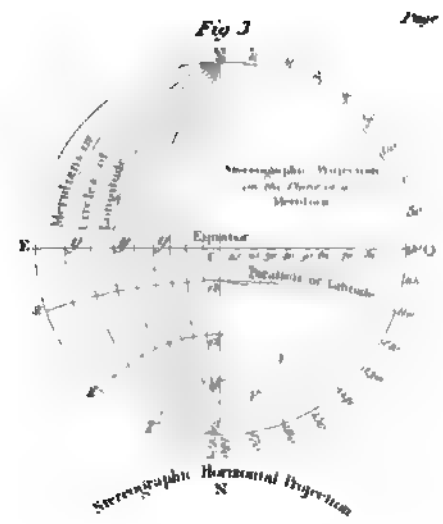

To draw the parallels of latitude. (Fig. 2.)—Latitude is the distance of any place from the equator, north or south. The same construction remaining, and the radii *CN*, *CS*, divided each into nine equal parts. Divide the circumference *A N B S* into thirty-six equal parts, each quadrant *AN*, *BN*, *AS*, *BS*, will be divided into nine equal parts, which, being again subdivided into ten equal parts each, will give us 360 equal parts or degrees.

To draw, now, the parallel of 30° north latitude, set one foot of the compasses in the point 30 on the axis meridian *NS*, and with any radius describe the circle *K T L*. Set, again, one foot of the compasses in the points 30, 30, in the circumference, and intersect the circle *K T L* in the points *x, x*, *a, a*. Through *x, x* and *a, a* draw the straight lines *x, x*, *a, a*, meeting each other in the point *R* of the axis *SN*, produced to *R*; and with *R* as a centre, and *R 30* as a radius, describe now the parallel of 30° north latitude. The same radius is used for 30° south latitude. After the same process the parallel of 60° north latitude is drawn, as may be easily conceived by inspecting the figure. And in this way proceed with all the other parallels in both hemispheres; as is evident from fig. 7.

This is the construction. The method of filling up the map, requires the attention of the delineator, in strictly observing the situations of objects or lines, as they respectively bear on the practice of map-making.

Prob. II. To project a map of the world on the plane of a meridian, according and by the stereographic projection of the sphere. (Fig. 3.)—**To draw the circles of latitude.**—Describe, from any centre *C*, the circle *R N Q S*, which will represent one-half of the earth's surface. Draw the diameters *EQ* and *NS*, intersecting each other at right angles. *EQ* is the equator, and *NS* the axis meridian. Divide the circumference into 360

Construction of Maps

equal parts; transferred 20, 30, 40 inches on the degree; from B to transfer the line 2040; transfer the position a 100-100; and from a draw the perpendiculars; and which produced the 100-100; N S produced in x. The point q is the centre from which to describe the great circle 100-100 or, the 50th degree of celestial latitude. The same radius will serve for the 60th parallel of north latitude; and for all the same manner all the other parallels in both hemispheres are drawn; as they are fully shown in fig. 10.

4. To draw the arcs of *globe-making*. The unequal distances of the equator, as indicated by the numbers 10, 20, 30, &c. on the radius GQ, and which are distances from No. 2, fig. 11. The points 20, 40, 60, &c. are centres, on which the circles of longitude by N. are to be drawn; draw the remaining circles, produce the diameter BQ, and, from N, through every tenth degree in the quadrant NQ, draw lines cutting that diameter produced, and the points of intersection will give the centres for the remaining circles of longitude; observe, however, that each centre is twenty degrees distant from the preceding one. For the circles of longitude in the other semi-hemisphere, the centres may be formed by setting off the proper distances on the diameter BQ, produced the contrary way.

Prob. III. To draw a map of the earth on the plane of a meridian, according to Dr. F. de la Hire's globular projection of the sphere. Fig. 44.—1. To draw the circles of latitude.—Describe the circle $HNQS$; draw two diameters EQ and ES at right angles; the former represents the equator, and the latter the axis meridiana. Divide the quadrant QSE into equal parts, 10, 20, 30, &c. From each of these divisions draw lines, as $R/20$, $Eg/30$, $Ed/40$, &c. Divide into two equal parts the portions $F/30$, $g/30$, $d/30$, &c. and from e , the point of division, let fall the perpendiculars $e/F/30$, and e/H produced till they cut the polar diameter extended indefinitely. The points P , A , G , are centres, from which the circles of latitude $g/30$, $d/30$, $c/40$, are to be described, and which mark the true representation of the parallels 20, 30, and 40 degrees of south latitude. In the same manner, draw the parallels for every tenth or fifth degree in that semi-hemisphere. To obtain those in the northern hemisphere, set off on the line EN produced in the opposite direction, the distances which served as centres of the southern parallels: and the northern ones may be described for every tenth degree of latitude.

2. To draw the circles of longitude. Fig. 4.—Divide the quadrant EN into equal parts, 10, 20, 30, &c. Divide also the quadrant EQ into 100 equal parts at 2° of $40'$ each, and let fall the perpendiculars r from the points. Set off, on the line NS produced, NS equal to as (see Fig. 3), then, lines drawn from k to 10, 20, 30, &c. in the quadrant WES , will divide the radius in the points 10, 20, 30, &c. through which the circles of longitude are drawn (see Fig. 4) in the following manner:—

To find the centre of the circle: S 30 N, join the points S 30, and N 30; divide the line into two equal parts in o , and let fall the perpendiculars $o 30$, and the point r , where they meet, is the centre of a circle of 30 degrees of longitude. The other centres may be found exactly in the same manner. Or the centres may be found, mechanically, from the following **TRIGONOMETRICAL TABLE OF RADII**—

Let the radius of the circle be divided into 100 equal parts by a scale; then the meridian or circle, of

Thus the radius of the circle of 10° of longitude is equal to the distance between 50 in the line EC , and 10 in the line QC ; the radius of that of 30° = the distance between 50 and 30 ; that of 50° between 50 in the line EC and a given point in EQ produced; which, taken from C , will be = 343 parts, of which radius is = 100 .

Prob. IV. To project a map of the earth stereographically, according to the horizontal projection of the sphere, and answering to the latitude of London, (see Dr. Blount's treatise on Maps.) See fig. 8. To draw the meridians.—With any radius, S C or S D, describe the circle C P D, which divide as usual into 30° , and draw

O D, P S, as straight lines to each other; then will P S be the first meridian, and the north and south extremities, A, B, C, D, E, F, G, H, I, K, L, M, N, O, P, Q, R, S, T, U, V, W, X, Y, Z, being the vertices of circles, are great circles of the sphere, intersecting each other in the zenith and nadir, and turning the horizon at right angles. On the quadrant D P set off D N = 47° = the latitude of London, and draw parallel to O D, W E, the east and west azimuth of the place. Bisect W E in the point X, which will be London, or the place of projection. The letters E, A, W, N, represent the four cardinal points, bearing East and west, north and south; from London (X), as the centre of the projection! Add P, the pole of the meridional projection, is also the pole of the horizontal projection. Describe now the meridians of the meridital projection C P D, observing to allow them to pass through the pole P, beyond the primitive circle, and to touch the horizontal projection in the segments W N E.

To describe the parallels of latitude.—Lay a ruler upon W, and move it to every degree, or every tenth degree of the meridian P Q continued, marking where it cuts the meridian N S, for through those points the parallels on this side of the pole must all pass. But, as they have not a common centre, the points through which they pass on the other side of the pole are found by moving the ruler along every tenth degree of the meridian P Q continued; for wherever the ruler intersects the meridian, N S will be the opposite points through which the parallels are to pass. Having now obtained the diameters of the parallels, we have only to bisect each of them, and with one half, as a radius describe the correspondent parallel. In this, the projection was now be completed, as directed in fig. No. 2.

Prob. V: By the globular projection of the sphere, to construct a map with azimuth lines, to shew the bearing and distance of all places within the map, from *Lbdoth*, or any other given place in the centre. (See fig. 6.) It will be perceived that, in this projection, the longitude and latitude of places are neglected, because the map is restricted to the bearing and distance only of places from a station in the centre. Describe a circle of any radius, cross it with two diameters; N S represents the meridian of the place assumed as the centre, or the north and south line; and W E, the east and west line, may be considered the parallel of latitude passing over the place. The intersection of the diameters, as at E, indicates the place in the centre. Divide each quadrant into 10P, of the exterior circle; and the inner circle into 10 equal parts; to indicate the points of the mariner's compass.

The lines radiating from *Z* are the bearing lines. The three concentric circles, described from the common centre *Z*, may be assumed as one degree each; and the scale will then contain 180 geographical, or 202½ English, miles. Suppose we place London in the centre; then, by the help of the Table of Latitude and Longitude, page 608, we may transfer, into this projection, all places within 180 miles of London.

The numbers 1, 2, 3 degrees, on the scale from the centre, are arbitrary, and may be reckoned 10, 20, 30 degrees; in which case our projection will embrace 1800 geographical, or 2000 English, miles. Or, if the radius, or scale, be divided into 4, 5, 6, or any given number of equal parts, each of those parts may represent 4, 5, 6, or 40, 50, 60, degrees. The scale in this projection must be considered a moveable slip of Bristol board, graduated according to the radius of the projection, and riveted on the map by means of a neat button. Its use is obvious; for, by moving it round, we determine the bearing and distance, at once, of all places from London, or any other place (Z), in the centre.

Fig. 7. represents the globular projection of the sphere; in which the rectangular figure *ABCD* represents the skeleton of the map of Asia. The parallelogram *EFGH*, the skeleton of the map of Africa. The rectangular figure *IKLM*, the skeleton of the map of North America. The parallelogram *NOPQ*, the skeleton of the map of South America. Projected on a large scale, these skeletons afford ample exercises for the display of gonies and tauts in the subsequent *filling up*, *shading*, *lettering*, and *colouring*.

Prob. VI. To construct a map of the world, on the plane of a meridian, according to the orthographic projection of the sphere. (Fig. 10.) To describe the meridians, which are ellipses.—If they be described through every tenth degree on the equator, the

distance of each successive meridian from the centre of the map, is found by means of the parallels drawn through the corresponding divisions of the circumference. If these elliptical meridians are drawn with a pair of elliptical compasses, through every eighth degree of the equator from the centre of the map, they will appear as in fig. 9.

To draw the parallels of latitude, which are straight lines.—If at 10° from each other, they are drawn parallel to the equator, they will indicate the parallels of latitude. But, if they be drawn through every eighth degree of latitude, they will appear as in fig. 9.

Note.—This projection is chiefly useful for astronomical purposes, to represent a sign of the Zodiac. It is obvious, that twelve such projections would furnish the means of depicting the twelve signs.

Prob. VII. To project, on the plane of the equator, a map of the world, according to the globular projection of the sphere. (Fig. 10.)—In fig. 10, the point R is distant from N equal to the sine of the sine of 45° in fig. 4. This point R is the place of the eye whence the spectator, supposing the sphere pellucid, views the entire hemisphere WSE. The lines which pass from 10, 20, 30, &c. in WS to the eye at R, cross the line WP obliquely in the points 10, 20, 30, &c. Thus, the equal division, originally 30, of the radius is obtained, and this is the principle of the globular projection of the sphere.

1. To draw the meridians, which, in this map, are straight lines, radiating from P, the pole.—Divide the circumference into 36 or 360 equal parts, and to each of these equal divisions draw straight lines, as seen in No. 2, and the meridians for one hemisphere, projected on the plane of the equator, are now laid down.

2. To draw the parallels of latitude, which, in this map, are concentric circles, described with their respective radii, from P the common centre.—From the observation, with which we have preceded this construction, we know that WP, the radius (No. 1), is divided into nine equal parts. Then, with the respective radii, P 10, P 20, P 30, &c. or No. 1, describe the concentric circles, as shown in No. 2, and one hemisphere is completed, so far as respects the projection of the meridians and parallels.

Countries, sea-coasts, towns or places, mountains, rivers, &c. may now be laid down from tables of Latitude and Longitude.

Prob. VIII. To construct a map of the world, on the plane of the equator, according to the stereographic projection of the sphere. (See fig. 11.)—As, in this projection, the eye of the observer is placed on the surface of the sphere, and in either pole, as at P (No. 1), the straight lines drawn from the equal divisions of the quadrant WS to the point P, cut the radius WP into unequal divisions, we observe, at once, the principle of the stereographic projection of the sphere, in which equal spaces on the surface of the earth are represented by unequal spaces on the projection; the space W 10 being double of P 30; and, consequently, if P 30 be 1, W 10 will be 2; and any quadrilateral continued between W 10 and 10° of latitude, on a projection on the plane of the meridian, will be four times the size of a quadrilateral comprehended by P 30 and 10° of latitude, because the square of 2 is 4, and the square of 1 is 1.

1. To project the meridians, which, in this map, are straight lines, radiating from P, the pole.—The directions given in that Problem apply perfectly to this; and the process is the same in both.

2. To draw the parallels of latitude, which, in this projection, are concentric circles.—Take P as the common centre, and with the radii P 10, P 20, P 30, &c. or No. 1, respectively, describe the concentric circles, which shall represent the parallels, as shown in No. 2.

The note subjoined to the last Problem is to be observed in the execution of this projection.

Prob. IX. To project a map, on the plane of the equator, according to the orthographic projection of the sphere. (See fig. 12.)—As the eye of the observer is supposed, in this projection, to be situated at an infinite distance from the surface of the sphere, all the lines which are drawn on it are straight lines. On this principle, the meridians would appear, to an eye so situated, as in No. 1, fig. 12; and the parallels would also be straight lines, as represented in fig. 9. But, on the plane of a meridian, a map constructed according to this projection has its meridians drawn elliptical, while the parallels are straight lines. (See fig. 9)

Whereas, on the plane of the equator, the same laws are observed as in the two last projections, and the meridians are radiating straight lines; while the parallels are concentric circles, described from the common pole.

1. To draw the meridians.—Proceed as in the two last problems for these meridians.

2. To draw the parallels of latitude.—Through the points 30, 20, 10, 0, 10, 20, 30, 40, 50, 60, 70, 80, and 90, of the semicircle NWS (No. 1), draw straight lines parallel to NPS; and the divisions 30, 20, 10, &c. on PWS, are the divisions which indicate the law of the projection, and the radii for the concentric parallels, which are respectively drawn on No. 2.

Scholium.—On reviewing these projections, the globular (No. 10) has decidedly the advantage of presenting equal spaces of latitude throughout its successive geographic quadrilaterals; the stereographic (fig. 11,) presents unequal spaces, diminishing towards the pole, but allowing us more space than the globular for those countries situated near the equator; and, in this respect, answering better than the other the conditions of the projection. The orthographic is the reverse of this last, as it allows to the polar regions more space than either of the other two; but then the countries contiguous to the equator are abandoned to a greater error in respect of latitude than even the polar regions in the stereographic projection. For special physical purposes, the globular is preferable; for astronomical use, the stereographic merits attention, when the signs of the Zodiac, or stars within the tropics, are to be laid down, to be seen from either pole; and the orthographic suits best the delineation of the Arctic or Antarctic circulations.

Prob. X. To project a map of Asia, according to the globular projection. (See fig. 13.)—Having drawn any meridian line AX, and assumed a distance A K for 10° of latitude, set off this distance nine times from A toward X. The point B, or 90, will be the pole. With the distance A K set off AB = A K; and cause the degrees of longitude on the equator correspond with those of latitude on a meridian of the sphere. At the point B, or 70° of latitude, set off AB, and draw a circle equal to 20° 53'; the number of geographic miles corresponding to 70°. Through the points B, D, &c. draw the concentric circles B C, D E, &c. constructed by the laws of decreasing longitude, perpendicular to the point X. This point (X) is, therefore, the common centre for all the parallels of latitude; and it is 30 degrees beyond the pole P, or at the same distance north of the parallel of 60 degrees, that the equator is south of it. On the equator, B C, set off the portion AB, or A D, as often as may be necessary to answer the conditions of the projection; and from each of these points, 50, 60, 70, &c. draw lines to the point X, and they will indicate the meridians, which are all straight lines. Set now, one foot of the compasses in the point X; and with the other describe the successive concentric circles, 10, 20, 30, &c. for the parallels of latitude. Through the point A draw a line at right angles to AX; raise the two perpendiculars W K, D W, and draw O W, completing the parallelogram O M L W. The degrees of longitude, as on the equator EAQ, or of latitude, as on the meridian 140°, may now be inserted on the parallel lines O M, W D, and O W. M D, &c. to 140°.

The outline of the Asiatic continent, as in the figure on the Plate, will materially assist the student; but his great resource must be in a Table of Latitude and Longitude. The eye is never to be depended on where the process of operation proceeds on such data as an accurate Table affords.

Prob. XI. To project a map, on a particular portion of the earth's surface, as of Italy, containing 6° of latitude, (viz. from the 38th to the 44th degree,) and 9° of longitude, (viz. from the 7th to the 16th of East longitude.) (See fig. 14.)—Draw the line EF, and in the middle of this line raise the perpendicular DC, which divide into six equal parts, or degrees of latitude, and through C draw the line EK parallel to EF. The projection is to be regulated, as to size, by the size of the paper. Divide a degree into 10 equal parts, or, if more exactness be required, and the number of miles which a degree of longitude contains in the latitude of 39°, viz. 60,62, and from any scale of equal parts, set off one half of the same, viz. 23° 31', on either side of D. Find the number of miles contained in a degree of longitude, in the latitude of 45°, viz. 42° 48'; and from the same scale of equal parts, from which the former measure was taken,

set off 21, 21½ on each side of C. Draw straight lines from E to K, and from E to F; divide them into the same number of parts as the line C.D. contains, and through the points draw parallel lines. Thus, I K F E is a projection for one degree of longitude, including six degrees of latitude.

Since the degrees must be so drawn, that the two diagonal lines in each map be equal to each other, they are to be projected in the following manner:—1. Take the distance from E to K, or from F to L, and, setting one foot of the compasses first in E, and then in F, describe the arcs L and M. Then set one foot first in L, and afterwards in K, and, with the same extent, draw the arcs N and O. 2. Take the distance between E and F, and set it off on the arcs described from E to N, and from F to O; then take the distance between L and K, and set it off from L to M, and from K to O. 3. Draw the lines between L and N, and M and O; divide them into degrees, and draw parallels from those points to the corresponding ones in the meridians I E and K F. The same method must be pursued in drawing all the other meridians and parallels which the conditions of the map require.

Should the map be very large, so much so that the compasses will not extend to the furthest degree, or from F to L, then draw one or more diagonals at once, and afterwards proceed with the rest. Thus, when the parallelogram P G E N and H Q O F are described, L I G P and K N Q H may be done. Number the degrees of latitude up both sides of the map, and the degrees of longitude on the top and bottom. Then make the proper divisions and subdivisions of the country; and, from a Table of Latitudes and Longitudes, it will be easy to set down in the map the principal places which should be found in it; for any town must be placed in the intersection of the lines which would indicate its latitude and longitude.

Thus Florence must be placed at A, where the circles of 43° 45' N. lat. and of 11° 3' 30" E. long. cut each other. And Naples must be placed at B, on the sea-shore, at 40° 45' 15" N. lat. and 14° 17' 30" E. long. In like manner, the mouth of a river, as the Tyber, for instance, must be set down; but, to describe its whole course, every turning must be laid down according to its latitude and longitude, and the towns and bridges also by which it passes.

On the projection we have now described, the diagonals being all equal, the number of meridians creates no defect in the representation, because equal spaces on the globe are represented by equal spaces on the map; consequently, places lying in the most remote degrees of longitude are as truly represented as those towards the middle of projection, and their distances will agree with a common measure; so that a pair of compasses, extended between any two places, and applied to the scale, will give the distance without further trouble. When the extent of country is not great, of which a map is to be made, as of a province or country, for example, the meridians, as to *mere*, are parallel in each other, and may be represented by straight lines. The whole, indeed, will differ so very little from a plane, that it will be sufficient to measure the distances of places in miles, and to lay them down in a plane right-lined map, of which the successive spaces, formed by the meridians and parallels, would be right-angled parallelograms, or, more properly, squares.

Prob. XII. To project a map of Europe.—Having drawn a line for the central meridian of the map, numbered in the Plate 20, 20, assume any convenient distance for 5°, and set it off on this meridian seven times from 35° to 70°; or, to obtain at once the common centre for all the parallels of latitude, set it off 11 times from 35, because $80 - 35 = 45$, and $45 \div 4 = 11$ equal the number of spaces of 5° between 35 and 80. The eleventh, or extreme division, is the pole; and 6½ degrees more, beyond it, will be the common centre from which the successive and concentric parallels of latitude are to be drawn.

To draw the meridians, take from a Table of decreasing Latitude, the number of miles in 36° latitude, and set this off as often as is necessary on each side of the central meridian (80°), on the parallel, or circle, of latitude 35°. From those points of division draw right lines to the common centre, and they will represent the meridians. But, because the meridians in this map are portions of circles, they are curved after the following manner:—Take the number of miles in 42°, and set

this off on the parallel of 40°; take from the Table the number of miles in 45°, and set this off on the parallel of 45°; take, for 50°, 60°, 65°, 70°, in like manner; and, having set off these measures on the concentric parallels as often as necessary, the points, when joined to indicate the meridians, will form as many segments of circles as there are meridians; and hence the construction is obvious.

For the purpose of drawing maps geometrically correct, it is necessary that schools, or preceptors, or students for themselves, provide a *bow-rule* and also *beam-compasses*. The former is purchased at any mathematical instrument maker's for half-a-guinea; and the latter seldom exceeds twenty five or thirty shillings. In drawing large maps, it will be found most convenient to fasten down the edges of the paper on an even board, which is covered with a smooth oil-cloth.

Prob. XIII. To construct a map, which shall contain the degrees of longitude and latitude of Great Britain.—This island lies between 50° and 60° N. latitude, and between 2° E. and 0° W. longitude. Having, therefore, chosen any unit of measure for a degree of latitude, the degrees of longitude must be proportioned to it. The length of a degree of longitude in latitude 54 is to one of latitude as 38:57 is to 60; that is to say, a degree of longitude is something more than half the length of a degree of latitude. The exact proportion may, however, be had by a diagonal line, which is divided thus:—Draw an indefinite line, of perhaps three inches; at each extremity raise two perpendiculars, which make equal to the assumed degree of latitude; complete the parallelogram by drawing its fourth side parallel to the first or base line; reduce the figure to two right-angled triangles by a diagonal. Divide this diagonal into 60 equal parts, and through the points of division draw lines parallel to the sides of the parallelogram, which are of equal length with the degree of latitude. The length of a degree of longitude in latitude 60°, is 30 00. Of course, on the diagonal scale, we take off this quantity where the number 30 is found. Then, on each side of the perpendicular, on which we set off the degrees of latitude, this measure 30 is set off three times to the east, and seven times to the west, to answer the conditions of the map. For the corresponding measures at 50° of latitude, take off at 38:57 on the diagonal scale, the proper quantity, and set it off three times to the east, and seven times to the west, of the perpendicular, or first meridian. Through the corresponding points, at 50° and 60° of latitude, draw now the meridians; and, through the equal divisions on the first meridian, draw the parallels of latitude. Then, from 3° east and from 7° west longitude, raise perpendiculars, which will complete the parallelogram that must contain the map. Having next divided into minutes and seconds the degrees of longitude and latitude, towns, cities, or rivers, or mountains, may be accurately laid down; since, by intersectional lines through the corresponding points of latitude and longitude, whatever is to be represented on the map may be readily depicted. A mariner's compass, on any such map, will show the bearing of one place from another.

Prob. XIV. To construct Mercator's Chart of the World.—Draw any indefinite line for an equator, marked a Equator a in the Plate. Assume any point on this line for the position of the first meridian, that is to say, the Meridian of Greenwich. Take any assumed distance in the compasses for 10° of longitude, or the unit of measure, set this off on the equator from zero (0), or the meridian of Greenwich, sixteen times on both sides of zero. Then will 160° of longitude be set off; because $16 \times 10 = 160$, which, multiplied by 10, gives 1600. Through those 30 equal divisions on the equator draw straight and parallel lines at right angles to the equator; these straight and parallel lines will be the meridians 0, 10, 20, 30, &c. and which, on the projection, are continued across the chart at every 20th degree of longitude, east and west of zero, or Greenwich.

MARANTA, Indian Arrow Root, a genus of the monandria monogynia class and order. Natural order scitamineæ. There are five species, of which the Indian arrow root has a thick, fleshy, creeping root, full of knots, from which arise many smooth leaves, six or seven inches long, and three broad towards their base, the stalks about two feet high, the ends of which are terminated by a loose bunch of small white flowers, standing upon peduncles two inches long; the flowers are cut into six narrow segments, pointed on their edges; these sit upon the

capsule, which flies wide, forms a roundish three-cornered arrow-root, because it was thought to extract the poison from wounds inflicted by the poisoned arrows of the Indians. The root washed, pounded fine, and bleached, makes a powder and starch; it is recommended as a proper food for infants, and is gelatinous like sago. It is a native of South America, and is cultivated in the West Indies.

MARBLE is a kind of stone, found in great masses, and dug out of pits or quarries. It is of so hard, compact, and fine texture, as readily to take a beautiful polish. There are infinite numbers of different kinds of marble. Some are of one simple colour, as white or black; others variegated with stripes, clouds, waves, and other figures, but all opaque, excepting the white, which, cut into thin pieces, becomes transparent. Marble is found in considerable quantities in most of the mountainous parts of Europe. Derbyshire is that county of England most abounding in this article. Italy is that part of Europe which produces the most valuable marble. The black and the milk-white marble, coming from Carrara, is within the duchy of Massa, and particularly esteemed. It is used to make statues and ornaments.

Polishing of marble is performed by first rubbing it well with a flint stone, or sand, till the strokes of the axe are worn off; then with pumice stone, and afterwards with emery. *Flora* of **MARBLE**, a kind of hardened mark, is not in domestic work, and framed like pictures, which sometimes fetch a high price. If kept at a distance from the eye, an inexperienced observer might mistake a vase of Florence marble for a drawing in distemper; for ruins of Gothic buildings, shattered fragments of cathedrals, and ruined walls, shattered bastions, and decayed towns, appear in the picture, which on a closer examination offers nothing but irregular spots, lines, and shades.

Imitation of marble is made from plaster of Paris, quick lime, sand, and blood, stones of different colours, and pieces of glass. These are all beaten to an impalpable powder, and mixed up to the consistency of a paste by the agency of beer, or some milk. When thoroughly dried in the form which is intended to be given to it, the mass on surface is rubbed with wet fine sand-paper, and polished with leather and oil.

MARBLING, the method of preparing and coloring the marbled paper. There are several kinds of marbled paper; but the principal difference of them lies in the forms in which the colours are laid out on the ground; some being disposed in whorls or circulations, some in jagged lengths, and others only in spots of a roundish or oval figure. The general manner of imaging each kind is, nevertheless, the same, being the dipping the paper in a solution of gum tragacanth, or, as it is commonly called, gum arabic; over which the colours, previously prepared with the gum and spirit of wine, are first spread. The peculiar apparatus necessary for this purpose, is a trough for containing the gum tragacanth and the colours, a comb for dipping the paper in the figure usually chosen; and a burnishing stand for polishing the paper. The trough may be of any kind of wood, and must be somewhat larger than the sheets of paper for marbling which it is to be employed; but the sides of it need only rise about two inches above the bottom, for by making it thus shallow, the less quantity of the solution of the gum will serve to fill it. The comb may be also of wood, and five inches in length, but should have brass teeth, which may be about two inches long, and placed at about a quarter of an inch distance from each other. The burnishing stone may be of jasper or agate; but as those stones are very dear when of sufficient largeness, marble or glass may be used, provided their surface be polished to a greater degree of smoothness. These implements being prepared, the solution of gum tragacanth must be made, by putting a sufficient proportion of the gum, which should be white, and clear from all foulness, into clean water, and letting it remain there a day or two, frequently breaking the lumps, and stirring it till the whole shall appear dissolved, and equally mixed with the water. The consistence of the solution should be nearly that of strong gum water used in miniature painting; and if it appear thicker, water must be added; or if thinner, more of the gum. When the solution is thus brought to a due state, it must be passed through a linen cloth, and being then put into the trough, it will be ready to receive the colours. The colours

employed for marine paintings, hills, clouds, and buildings, but the two last are too hard and glaring; and as they are mixed with vermilion or lake, to bring them to a softer cast; and with respect to the vermilion and lake, they are too dear for common purposes. For yellow, Dutch pink, and yellow ochre, may be employed; for blue, Prussian blue and verditer may be used; for green, verdigris, a mixture of Dutch pink and Prussian blue, or verditer, in different proportions; for orange, the orange lake, or a mixture of vermilion or red lead with Dutch pink; for purple, rose-pink and Prussian blue. These several colours should be ground with spirit of wine, till they be of a proper fineness; and then at the time of using them, a little fish-gill, or, in default of it, the gall of a boar, should be added, by grinding them over again with it. The proper proportion of the gall must be found by trying them; for there must be just so much as will suffer the spots of colour, when sprinkled on the solution of the gum tragacanth, to join together, without intermixing or running into each other. When every thing is thus prepared, the solution of the gum tragacanth must be poured into the trough, and the colours being in a separate pot, with a pencil appropriated to each, must be sprinkled on the surface of the solution, by shaking the pencil, charged with its proper colour, over it, and this must be done with the several kinds of colour desired, till the surface be wholly covered. When the marbling is proposed to be in spots of a simple form, nothing more is necessary; but where the whorls or snail-shell figures are wanted, they must be made by means of a quill, which must be put among the spots to turn them about, till the effect be produced. The jagged lengths must be made by means of the comb above described, which must be passed through the colours from one end of the trough to the other, and will give them that appearance; but if they be desired to be pointed both ways, the comb must be again passed through the trough in a contrary direction; or if some of the whorls or snail-shell figures be required to be added, they may be yet made by the means before directed. The paper should be previously prepared for receiving the colours, by dipping it over-night in water; and laying the sheets on each other with a weight over them. The whole being thus ready, the paper must be held by two corners, and laid in the most gentle and even manner on the solution covered with the colours; and there softly pressed with the hand, that it may bear every where of the solution. After which, it must be raised and taken off with the same care, and then hung to dry across a proper comb, supported near at hand for that purpose; and in that state it must continue till it be perfectly dry. If then remains only to give the paper a proper polish, in order to which, it is first rubbed with a little soap, and then must be thoroughly smoothed by the glass polisher, such as are used for linen, and called the calendar glasses. After which it should be again rubbed by a betherisher of jasper or agate; or in default of them, of glass ground to the highest polish; for on the perfect polish of the paper depends in a great measure its beauty and value. Gold or silver powders may be used where desired, along with the colour, and require only the same treatment as them, except that they must be first tempered with gum water.

Marbling of books or paper is performed thus:—Dissolve four ounces of gum arabic in two quarts of fair water; then provide several colours mixed with water in pots and shells, and with pencil put a little to each colour, sprinkle them by way of intermixture upon the gum water, which must be put into a trough or some broad vessel, then with a stick curl them, or draw them out in streaks; to as much variety as may be done. Having done this, hold your book or books close together, and only dip the edges in, on the top of the water and colours, very lightly; which done, take them off, and the plain impression of the colours in mixture will be upon the leaves, doing as well the order as the front of the book in the like manner. Marbling a book on the covers is effected by forming clouds with aquafortis or spirit of vitriol mixed with ink, and afterwards glazing the covers. See BOOK-BINDING.

MARCH. According to common computation, this is considered the third month in the year, but with the Romans it had the honour of being the first. When, however, chronology authenticates the years that have elapsed since the Saviour's incarnation, the calculation always begins with the twenty-

make the masts and the mast above the water on gravity, the greater will be the strain of the sail which they are enabled to present to the wind; so far an additional height seems to be a disadvantage. But this advantage is diminished by the circular movement of the mast, which operates to make the vessel steady to its efforts, and this inclination is increased in proportion to the additional height of the masts; an inconvenience which it is necessary to guard against; thus what is gained upon one hand is lost upon the other. To reconcile these inconveniences it is certain that the height of the mast ought to be determined by the inclination of the vessel, and that the point of greatest inclination should be the turn of this height, where the centre of gravity. See the article *TACKLE*. With regard to the general practice of determining the height of the masts, according to the different rates of the ships in the royal navy, see also the article *SHIPS*. In order to secure the masts, and counterbalance the strain they receive from the effort of the sails, impressed by the wind and the agitation of the ship at sea, they are suspended by several strong ropes extended from the masts down the outside of the vessel, called *brides*, (see that article.) They are further supported by other ropes, stretched from their heads towards the forepart of the vessel. See the article *RIGGING*. In the British navy, masts are proportioned to the extreme breadth of the ship from waist to out. At this point, and to the mast in all ships down to 80 tons, one inch diameter to every yard in length. For 80 and 40 tons, 1 1/2 inches diameter to one yard in length. For 34 tons, 1 1/2 inches diameter to one yard in length. All top masts are one eighth of an inch in diameter to one yard in length. The fore-top mast as large as the main-top mast. The top-gallant mast one inch to a yard. The mizzen mast 1/2 inch to one yard in length. The mizzen-top mast five-eighths of an inch to one yard in length. The bowsprit an inch and a half to one yard. The jibboom seven-eighths of an inch to a yard. The proportion for masting ships in the merchant's service is generally regulated by the judgment and experience of the commander.

General Proportion for the Length of Masts.

1000' main mast	100	90	80	70	60	50	40	30	20	10	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0

	---	---	---	---

The Dimensions of Masts for East India Ships are

Length in Feet	Diameter in Inches
Main Mast	100
Top Mast	80
Fore Mast	60
Mizzen Mast	40
Fore Top Mast	30
Mizzen Top Mast	20
Fore Top Gall Mast	15
Mizzen Top Gall Mast	10
Bowsprit	150

Armed Mast. Is a mast that is made of more than one tree. To Mast a Ship, is to hoist her masts up her in the usual manner, or of a sheer bulk. See those articles.

Springing a Mast, is when it is broken by foul weather.

Over Mast, or Part Mast, is said of a ship whose masts are too tall or too heavy, which makes her lie too much down by the wind, and labour too much a-hull.

Under Mast, or Low Mast Ship, are such whose masts on the contrary are too short or light; in which case she does not bear so great a sail as should give her true way.

Chalk Ballasted Masts for Sailing Vessels. The object of this invention is, by having the mast, rigging, &c. placed in a ballasted passon or box of a semicircular shape, supported fore and aft on pins, &c. in two deck beams; that the mast, &c. shall alone be acted on by the wind; and (as shown by the figure,) leave the vessel itself perfectly upright, when disengaged upon a wind.

Explanation of the figures. Fig. 1, a, a section of the hull of the vessel; b, a section of the swinging cassoon, with the blays, pen-nants, &c. fastened to it; and the box containing the ballast; c, the point of suspension on the deck beams; Fig. 2 is a plan of the sailing boat, containing the cassoon b, and swinging upon the pivots c c. Mechanical skill will be requisite in the construction of the parts for strength, to sustain the ballast: pins of three inches diameter would sustain about thirty or forty tons. The forestay is to be hooked to the stern head.

The advantages proposed by Mr. Clint by this construction are *first*, perfect safety; as he considers it impossible that a vessel on this construction could capsize. *Secondly*, the vessel being always upright, is constantly on what is termed her *hull*, and is always in her *trim*; whereby she will sail faster, and go better to windward. *Thirdly*, the support for the mast, &c. being within the vessel, the width of beam may be diminished to one half, whereby the vessel will acquire length, and go faster. *Fourthly*, the ballast being suspended in the air is of more effect than ballast placed in the bottom; the latter being identified with the vessel, and the water loses as much of its weight as its specific gravity; while the former being independent of the water, and maintaining all its weights, a much smaller quantity will be required to steady the mast, and the vessel itself requiring none, a great degree of buoyancy is obtained. The truth of this position may be ascertained by holding in the hand a weight in the air, and holding it in the water. A vessel on this principle has been constructed, of the following dimensions:—Length 25 feet, breadth 5 do. depth 2 1/2 do. space for the cassoon 5 feet square, cassoon a good fit to the same size. She was rigged with one mast of ninety feet, carrying a gall and foresail, and containing fifty yards of cloth. To those conversant with sailing, this quantity of rigging must appear very extraordinary; but her capacity to carry it results from the principle mentioned in the position. This invention is intended only for such vessels as are not employed in the carrying of cargoes, of which class are revenue cutters, pleasure and pilot boats, carrels, nor is it intended for vessels above seventy tons, which may have the box decked in.

When the vessel is launched before the places of the masts are determined, extend a rope A B, in the following figure, from

to the head to the stern. To the extremities A and B attach two

other ropes, *A.B.*, and apply to the other ends of these ropes two mechanical powers, so that the ship (according to the direction of *A.B.*) parallel to itself. The whole being thus disposed, let a suitable timber, *Z*, fixed upon the rope *A.B.*, have another rope *Z.R.* attached to it, whose other end, connected with a mechanical power, is equal to the two other powers *A* and *C*. This last being applied to the same vessel, in such manner as, to take off the effect of the two others by adding upon the rope *A.B.* (see *fig.*), to discover some point *Z*, by the parallelism of the ropes *A.D.*, *B.C.*, freely extended with the rope *Z.R.*, and then *Z.R.* will be the axis of the equilibrium of the vessel's resistance, and, by consequence, the main mast should be planted in the point *Z*. The figures *E.B.E.*, are also intelligible, on other ships, by which this experiment is applied. With regard to the situation of the other masts, it is necessary in the same manner to discover a point, so that the direction of the two mechanical powers operating, will be parallel to the axis of resistance *R.Z.*, already found.

MASTER OF A SHIP, is the first degree taken up in foreign universities, and for the most part in those of Scotland; but the second in Oxford and Cambridge, candidates not being admitted to that honour till they have studied seven years in the university.

MASTERS IN CHANCERY. The masters in Chancery are assistants to the Lord Chancellor and Master of the Rolls; of these there are some ordinary and others extraordinary: the masters in ordinary are twelve in number; some of whom sit in court every day during the term, and have referred to them in the ordinary orders for stating accounts, and computing damages, and the like; and they also administer oaths, take affidavits, and acknowledgments of deeds and recognisances. The masters extraordinary are appointed to sit in the country, beyond ten miles' distance from London.

MASTERS OF THE FACULTIES, an officer under the archbishop of Canterbury, who grants licences and dispensations.

MASTERS OF THE HORSE, a great officer of the crown, who orders all matters relating to the king's stables, races, breed of horses, &c.

MASTERS OF THE ORDNANCE, a great officer who has the chief command of the king's ordnance and artillery.

MASTERS OF THE ROLLS, a patent officer for life, who has the custody of the rolls of parliament, and patents which pass the great seal, and of the records of chancery, &c. In absence of the chancellor, he sits as judge in the court of chancery; at other times he hears causes in the rolls chapel, and makes orders; he hath a writ of summons to parliament.

MASTERS OF A SHIP, the same with captain in a merchantman; but in a king's ship he is an officer who inspects the provisions and stores, takes care of the rigging and of the ballast, and gives directions for stowing the hold; and navigates the ship under the directions of his superior officer.

MASTERS AT ARMS, in a king's ship, an officer who, daily by turns, as the captain appoints, is to exercise the petty officers, and ship's company, to place and relieve sentinels, to see the candles and fire put out according to the captain's orders, to take care the small arms are kept in good order, and to observe the directions of the lieutenant at arms.

MASTERS OF THE TEMPLE, since the dissolution of the order of the Templars, the spiritual guide and master of the Temple, is so called, which was the denomination of the founder and his successors.

MASTERS OF THE WARDROBE, an officer under the lord chamberlain, who has the care of the royal robes, &c.

MASTERS AND SERVANTS. In London and other places, the mode of hiring is by what is commonly called a month's warning or a month's wages; that is, the parties agree to separate on either of them giving to the other a month's notice for that purpose, or, in lieu thereof, the party requiring the separation to pay or give up a month's wages. But if the hiring of a servant be general, without any particular time specified, it will be construed to be a hiring for a year certain; and in this case, if the servant departs before the year, he forfeits all his wages. And where a servant is hired for one year certain, and so from year to year as long as both parties shall agree, and the servant after upon the second year, he must serve out that year, and is not merely a servant at will after the first year. If

a woman servant marry, she must nevertheless serve her term. If a servant be disabled in his master's service, by an injury received through another's default, the master may recover damages for loss of his service. And a master may not only maintain an action against any one who entices away his servant, but also against his servants, and if, without any enticement, a servant leaves his master without just cause, an action will lie against another who retains him without knowledge of such departure. A master has a right to expect exact fidelity and obedience in all his lawful commands; and to enforce this, he may correct his servant in a reasonable manner. In defence of his master, a servant may justify against another, and though death should ensue, it is not murder, in case of any unlawful attack upon his master's person or property. Acts of the servant are in many instances deemed acts of the master, and he is answerable for them, when they are pursuant to his authority. If a servant commit an act of trespass by command or encouragement of his master, the master will be answerable. But in an action, his servant is not excused, as he is bound to obey the master in such things only as are honest and lawful. If a servant of an innkeeper robs his master's guest, the master is bound to make good the loss. Also, if a waiter at an inn sells a man bad wine, by which his health is impaired, an action will lie against the master. In like manner, if a servant be frequently permitted to do a thing by the tacit consent of his master, the master will be liable. If a servant is usually sent upon trust with any tradesman, and he takes goods in the name of his master, upon his own account, the master must pay for them; and also, if he is sent sometimes on trust, and at other times with money. But if a man usually deals with tradesmen himself, or constantly pays them their money, he is not answerable for what his servants may take up in his name. So it is, if the master never had any special dealings with the tradesman, but the contracts have always been between the servant and the tradesman, and the master has regularly given his servant money for payment of every thing had on his account, the master shall not be charged. Or if a person forbid his tradesman to trust his servant on his account, and he continues to purchase upon credit, he is not liable. The act of a servant, though he has quitted his master's service, has been held to be binding upon the master, by reason of the further credit given him on his master's account, and its not being known to the party trusting that he was discharged. The master is also answerable for any injury arising by the fault or neglect of his servant, when executing his master's business. If a smith's servant lame a horse whilst shoeing him, or the servant of a surgeon make a wound worse, an action for damages will lie against the master, and not against the servant. A master is likewise chargeable for any nuisance occasioned by his servants, to the damage or annoyance of any individual or the common nuisance of his majesty's subjects. A servant is not answerable to his master for any loss which may happen without his wilful neglect, but if he be guilty of fraud or gross negligence, an action will lie against him by his master. A master is not liable in trespass for the wilful act of his servant, as by driving his master's carriage against another, without the direction or assent of his master, no person being in the carriage when this act was done. But he is liable to answer for any damage arising to another from the negligence or unskillfulness of his servant acting in his employ, as for negligently driving against another.

MASTICATION, in Medicine, the action of chewing, or of agitating the solid parts of our food between the teeth, by means of the motion of the jaws, the tongue, and the lips, whereby it is broken into small pieces, impregnated with saliva, and so fitted for deglutition and a more easy digestion.

MASTICH, in the materia medica, when pure is in the form of little round drops or tears of a very pale amber. When slightly warmed, this resin has a faint and rather pleasant odour, which becomes stronger and more grateful when it is melted. In Turkey, mastich is in great request among women as a masticatory. In other countries it is employed medicinally in fumigations; and by painters and other artists in the composition of the tougher kinds of varnishes.

MATCH, a kind of rope slightly twisted, and prepared to retain fire for the use of artillery, mines, fireworks, &c.

MATCHING, in the wine trade, the preparing vessels to preserve wines and other liquors, without their growing sour or vapid. The method of doing it as follows:—Melt brimstone in an iron ladle, and when thoroughly melted dip into it slips of coarse linen cloth; take these out, and let them cool; this the wine coopers call a match. Take one of these matches, set one end of it on fire, and put it into the bung-hole of a cask; stop it loosely, and thus suffer the match to burn nearly out; then drive in the bung tight, and set the cask aside for an hour or two. At the end of this time examine the cask, and you will find that the sulphur has communicated a violent pungent and suffocating scent to the cask, with a considerable degree of acidity, which is the gas and acid spirit of the sulphur. The cask may after this be filled with a small wine which has scarce done its fermentation; and bunging it down tight it will be kept good, and will soon clarify: this is a common and very useful method, for many poor wines could scarce be kept potable even a few months without it.

MATERIA MEDICA. The materia medica includes all those substances which may contribute to the restoration of health.

MATHEMATICS, from *Mathema*, a science. The science which contemplates whatever is capable of being numbered or measured. Mathematics are commonly distinguished into speculative and practical, pure and mixed. *Speculative Mathematics*, is that which barely considers the properties of things; and *Practical Mathematics*, that which applies the knowledge of those properties to some uses in life. *Pure Mathematics* is that branch which considers quantity abstractedly, and without any relation to matter or bodies, as Arithmetic and Geometry. *Mixed Mathematics*, considers quantity as subsisting in material being; for instance, length in a pole, depth in a river, height in a tower, &c. *Pure Mathematics*, again, either considers quantity as abstract or discrete, these words are synonymous in this sense, and so computable as Arithmetic; or as concrete, and so measurable as Geometry. *Mixed Mathematics* is very extensive, and is distinguished by various names, according to the different subjects it considers, and the different views in which it is taken, such as astronomy, geography, optics, hydrostatics, navigation, &c.

MATRICARIA PARTHENIUM. *Common wild Feverfew. The Land Flowers*.—Simon Paull relates, that he has experienced happy effects from it in obstructions of the uterine evacuation. I have often seen, says he, from the use of a decoction of matricaria and chamomile flowers with a little mugwort, hysterical patients instantly relieved, and the patient from a lethargic state brought as it were to life again. Matricaria is likewise recommended in sundry other disorders, as a warm stimulating bitter: all that bitters and carminatives can do, says Geoffroy, may be expected in this. It is undoubtedly a medicine of some use in these cases, but not perhaps equal to chamomile flowers alone, with which the matricaria agrees in sensible qualities, except in being weaker.

MATTER, in Philosophy, whatever is extended, and capable of making resistance; hence, because all bodies, whether solid or fluid, are extended and do resist, we conclude that they are made up of matter. That matter is one and the same thing in all bodies, and that all the variety we observe arises from the various forms and shapes it puts on, seems very probable, from a general observation of nature in the generation and destruction of bodies: thus, water rarefied by heat becomes vapour: a great collection of which forms clouds; these condensed descend in hail or rain; part of this collected on the earth constitutes rivers; another part mixing with the earth, enters into the roots of plants, and expands itself into various species of vegetables. In each vegetable it appears in one shape in the root, another in the stalk, another in the flowers, &c. Hence various bodies proceed; from the oak, houses, ships, &c.; from hemp and flax we have thread; thence our various kinds of linen; these degenerate into rags, which receive from the mill the various forms of paper, &c.

According to Newton, it seems probable that God in the beginning formed matter into solid, massy, impenetrable, moveable particles, or atoms, of such sizes and figures, and with such other properties, and in such proportion to space, as most conduced to the end for which he formed them; these primi-

tive particles being solids, are incomparably harder than any porous bodies compounded of them, no ordinary power being able to divide what God himself made one in the first creation. While these particles continue entire, they may compose bodies of the same nature and texture in all ages; but should they wear away, or break in pieces, the nature of things depending on them may be changed. Water and earth composed of old worn particles and fragments of particles, would not be of the same nature and texture now, with water and earth composed of entire particles in the beginning; and therefore, that nature may be lasting, the changes of corporeal things are to be placed only in the various separations and new associations of motions of these permanent particles, compound bodies being apt to break, not in the midst of solid particles, but where those particles are laid together and only touch in a few minutes. Dr. Berkeley argues against the existence of matter itself, and endeavours to prove that it has no existence out of the mind. Some late philosophers have advanced a new hypothesis concerning the nature and essential properties of matter, as Boecovich, in his "Theoria Philosophiæ Naturalis;" who supposes that matter is not impenetrable, but consists of physical points only, endued with powers of attraction and repulsion, taking place at different distances; that it is surrounded with various spheres of attraction and repulsion, in the same manner as solid matter is supposed to be. Provided therefore any body move with a sufficient degree of velocity, or have a sufficient momentum to overcome any power of repulsion that it may meet with, it will find no difficulty in making its way through any body whatever. If the velocity of such body in motion be sufficiently great, Boecovich contends that the particles of any body through which it passes, will not even be moved out of their place by it. With a degree of velocity something less than this, they will be considerably agitated, and ignition might perhaps be the consequence, though the progress of the body in motion would not be sensibly interrupted; and with a still less momentum, it might not pass at all. Dr. Priestley, and some others of our own country, entertained the same opinion. In conformity to this hypothesis Priestley maintains that matter is not that inert substance that it has been supposed to be; that powers of attraction or repulsion are necessary to its being; and that no part of it appears impenetrable to other parts. Accordingly, he defines matter to be a substance possessed of the property of extension, and of powers of attraction or repulsion, not distinct from matter, and foreign to it, but absolutely essential to its nature and being; so that when bodies are divested of these powers they become nothing. In another place, Priestley has given a somewhat different account of matter; according to which it is only a number of centres of attraction and repulsion, or, more properly, of centres not divisible, to which divine agency is directed; and as sensation and thought are not incompatible with these powers, solidity or impenetrability, and consequently a *vis inertia*, only having been thought repugnant to them, he maintains that we have no reason to suppose that there are in man two substances absolutely distinct from each other. But Dr. Price, in a correspondence with Dr. Priestley, published under the title of "A Free Discussion of the Doctrines of Materialism and Philosophical Necessity," 1778, suggested a variety of unanswerable objections against this hypothesis of the penetrability of matter, and against the conclusions that are drawn from it. The *vis inertia* of matter is the foundation of all that is demonstrated by natural philosophy concerning the laws of the collision of bodies. This is the foundation of Newton's philosophy, and especially of his three laws of motion. Solid matter has the power of acting on other matter by impulse; but unsolid matter cannot act at all by impulse; and this is the only way in which it is capable of acting by any action that is properly its own. If it be said that one particle of matter can act upon another without contact and impulse, or that matter can, by its own proper agency, attract or repel other matter which is at a distance from it, then a maxim hitherto universally received must be false, that "Nothing can act where it is not." Newton, in his letters to Bentley, calls the notion that matter possesses an innate power of attraction, or that it can act upon matter at a distance, and attract and repel it by its own agency, an absurdity into which he thought no one could possibly fall. And in another place he

emphatically denying the notion of impenetrability, and asserting power to show that he did not take it to be an essential property of matter. If the same kind of reasoning pursued, it must appear that matter has not the power of attracting and repelling; that this power is the power of some foreign cause, acting upon matter according to stated laws; and consequently that attraction and repulsion not being actions, much less inherent qualities of matter, on such, it ought not to be defined by them. And if matter has no other property, as Dr. Price says asserts, than the power of attracting and repelling, it must be a non-entity; because this is a property that cannot belong to it. Besides, all power is the power of something, and yet if matter is, nothing the very idea of it is a contradiction. If matter be not solid extension, what can it be more than mere extension. Further, matter that is not solid, is the same with pore; and therefore it cannot possess what philosophers mean by the momentary or figure of bodies, which is always in proportion to the quantity of matter in bodies void of pore.

MATRIX, or *mother lark*, the stone in which metallic ores are found enveloped.

, MATROSSSES, are soldiers in the train of artillery, who are next to the gunners, and assist them in loading, firing, and managing the great guns.

MAUNDY THURSDAY, is the Thursday, in the passion week, called Maundy or Placid Thursday, from the command which our Saviour gave his apostles to commemorate him in the Lord's Supper, which he this day instituted, our from the new commandment that he gave them, to love one another, after he had washed their feet in token of his love to them.

MAUPERTUIS, **Pierre Louis MORGAN**, a celebrated French mathematician and philosopher, was born at Malesherbes, and was there privately educated, till he attained his 16th year, when he was placed under the celebrated professor of philosophy, M. Le Blanc, in the college of La Marche, near Paris, while M. Guinard, of the Academy of Sciences, was his instructor in mathematics. In 1723 he became a member of the French Academy, and six years after a fellow, of the Royal Society of London. In 1736 he was sent, with other astronomers, to the North, to determine the figure of the earth, which service they performed with reputation. At the invitation of the Princes of Prussia, afterwards Frederic the Great, he went to Berlin, and was appointed president and director of the Academy there. He died at Basel, in 1758.

MAA.I.L.L.I. She ANXIOUS.

MAXIM, an established proposition or principle, in which some at times use the same with axiom. See **AXIOM**.

MAXIMA and MINIMA, in Analysis and Geometry, are the greatest and least value of a variable quantity; and the method of finding these greatest and least values, is called the *Method of Maxima and Minima*, which forms one of the most interesting lectures in the modern analysis. This subject was considered geometrically by some of the most ancient mathematicians, particularly by Apollonius, in the 5th book of his Conics, and there are still a few problems of this kind, which succeed better by the geometrical than by the analytical method; their number, however, is very limited, compared with those, which may be elegantly formed with analysis. The method of maxima and minima, according to the analytical doctrine, first arose at the beginning of the seventeenth century, after the invention of New Cartes for expressing the properties of curve lines by means of algebraical equations, and classing them into different orders according to the degree of the equation which expressed the relation between the absciss and ordinate. Besides the method of New Cartes, we have also those of Fermat, Hudde, Huygens, Sluze, and some others, which are now all supplanted by the general and elegant method of Fluxions.

MAXIMI is, in Mathematics, denotes the greatest quantity obtainable in a given case. If a quantity conceived to be generated by motion, increases or decreases till it arrives at a certain magnitude or position, and then, on the contrary, grows less or greater, and it be required to determine the said magnitude or position, the question is called a problem, de maximis et minimis. Thus let a point m move uniformly in a right line, from A towards B , and let another point n move, after it, with a velocity either increasing or decreasing, but so that it

mag at a certain position, Ω , become equal to that of the former point m , moving uniformly.

This being premised, let the motion of n be first considered as an increasing one, in which case the distance of n behind m will continually increase, till the two points arrive at the contemporary positions C and D ; but afterwards it will again decrease, for the motion of n till then being slower than that of m , it is also slower than that of the preceding point m , (by the hypothesis,) but becoming quicker afterwards than that of m , the distance mn (as has been already said) will again decrease, and therefore as a maximum, or the greatest at all, when the celerities of the two points are equal to each other. But if n arrives at D with a decreasing celerity, then its motion being first swifter, and afterwards slower than that of m , the distance of mn will first decrease and then increase, and therefore is a minimum, or the least of all, in the forementioned circumstances. Since then the distance mn is a maximum or a minimum, when the velocities of m and n are equal, or when the distance increases as fast through the motion of m , as it decreases by that of n , its fluxion at that instant is evidently equal to nothing. Therefore as the points m and n may be conceived such that their distance mn may express the measure of any variable quantity whatever, it follows, that the fluxion of any variable quantity whatever, when a maximum or a minimum, is equal to nothing. The rule therefore to determine any flowing quantity is an equation proposed, to an extreme value, is having put the equation into fluxions, let the fluxion of that quantity whose extreme value is sought, be supposed equal to nothing, by which m and all those members of the equation in which it is found will vanish, and the remaining ones will give the determination of the maximum or minimum required.

See FLUXIONS.

May. Y., reckoning from January, this is the fifth month in our year; or the third, if we begin, as the ancient Romans did, with March. By Romulus it was called *Maius*, out of respect to the senators and nobles of his city. Some, however, have thought that the name is derived from *Maior*, the mother of *Mercurius*, to whom sacrifices were offered on the first day of this month. May was supposed by the ancients to be under the immediate protection of *Apollo*. In it they kept the festival of *Luna Maia*; also that of the goddess called *Leucorria*, and the ceremony of the expulsion of the kings. In this month the seasons *Grævis*, the earth teeming with vegetable life, the trees are adorned with blossoms, and the gardens are perfumed with the fragrance of flowers.—The calendar of animated nature for May, sound London, brings the cuckoo and turtle-dove, the glow-worm, and the fern owl, or goat-sucker.—In Vegetable nature, the lily of the valley, the ruby-tree, the oak, ash, sweet chestnut, barberry, and lime trees bud or blossom. We is now in the ear.—In the Kitchen garden, sow, prick, propagate, plant, transplant, attend to routine culture, and destroy insects and vermin. In the hardy fruit department, plant, prune, and attend to routine culture. In the culinary department attend to glass-casing, the pinery, and forcing department. Much is to be done in the flower garden, open ground and hot-house departments, as also in the pleasure ground and shrubbery. Fell old oaks and other building trees, and young oaks, because the wood bends quicker while the sap is flowing.—Of fish we have the same kinds in season this month as in April, which see, as also of meat, and poultry. Vegetables are more abundant, and to our winter stores of fruits there are now added strawberries, cherries, melons, gooseberries, and currants.

May Weed, in Botany, is a troublesome weed, which resembles wild chamomile. It is a trailing perennial plant, the branches of which put forth roots at every joint. By these means, and by scattering its seeds in the fields long before the corn is sown, it multiplies without the possibility of prevention. Its flowers in May, and from this circumstance derives its name. It is chiefly extirpated by summer following, and by burning the roots, collected by good harrowing. Many other weeds, together with various fruits, flowers, and natural productions

best the name of May, from their supposing that they stood on it in the grand state of perfection, but it was only a soft soil.

MAYER, TOMAS, a German astronomer and mechanician, was born at Mumpach, in Wirtemberg, in the year 1723; and in 1761 he was nominated mathematical professor at the university of Göttingen, and soon after was admitted a member of the Royal Society in that town. From that time, every year of his life was distinguished by discoveries in geometry and astronomy. He invented many useful instruments; he applied himself to study the theory of the moon; he extended his observations to the planet Mars and the fixed stars, determining the place of the latter, and ascertaining that they possess a certain degree of motion relative to their respective systems. Towards the close of his short life the magnetic needle engaged his attention, to which he assigned more celestial laws than those before received. To test his hypotheses he applied with exact indefatigable assiduity what he did literally mean with labour, to 1779, at the age of thirty-nine years, to the **METHOD**, a wholesome vegetable liquor prepared with honey and water. One of the best methods of preparing mead is as follows:—Into twelve gallons of water put the whites of six eggs, mixing them well together and to the mixture adding twenty pounds of honey. Let the liquor boil an hour; and when boiled, add cinnamon, ginger, cloves, mace, and nutmeg. As soon as it is cold, put a spoonful of yeast into it, and turn it up, keeping the vessel still as it works; when it has done working, stop it up close; and, when fine, bottle it off for use. The author of the Dictionary of Chemistry directs to choose the whitest, purest, and best of the honey, and to put it into a kettle with more than its weight of water; a part of this liquor must be evaporated by boiling, and the liquor remaining, till its consistency is such, that a fresh egg shall be supported on its surface without sinking more than half its thickness into the liquor; then the liquor is to be strained and poured through a funnel into a barrel, which ought to be nearly full, must be exposed to a heat as equable as possible, from 90 to 97, or 98 degrees of Mr. Fahrenheit's thermometer, taking care that the bung-hole be slightly covered, but not closed. The phenomena of the spirituous fermentation will appear in this liquor, and will subsist during two or three months, according to the degree of heat; after which they will diminish and cease. During this fermentation, the barrel must be filled up occasionally with more of the same kind of liquor of honey, some of which ought to be kept apart on purpose to replace the liquor which flows out of the barrel in froth. When the fermentation ceases, and the liquor has become very viscous, the barrel is then to be put into a cellar, and well closed; a year afterwards, the mead will be fit to be put into bottles. Mead is a liquor of very ancient use in Britain. See **BAZAR**.

MEAD, DR. RICHARD, a celebrated English physician, was born at Stepney near London, where his father, the Rev. Mr. Matthew Mead, had been one of the two ministers of that parish; but in 1693 was ejected for nonconformity, but continued to preach at Stepney till his death. As Mr. Mead had a handsome fortune, he bestowed a liberal education upon 13 children, of whom Richard was the eleventh; and for that purpose kept a private school in his house.

MEADOW, in its general signification, means pasture or grass-lands, usually mown for hay; but it is more particularly applied to lands that are so low as to be two months entire to grass upon them in winter without spoiling the sward.

MEADOW-SWART. *Sparganium Filipedula*. The roots of this, in Sweden, are ground and made into bread.

MEAL, the flour of grain. The colour and weight are the two things which denote the value of meal or flour; the whiter and heavier, other things being alike, the better it always is.

MEAN, in general, denotes the middle between two extremes: thus we say, the mean distance, mean proportion, &c.

MEAN, ARITHMETICAL, is half the sum of the two extremes, as 4 is the arithmetical mean between 2 and 6; for $\frac{2+6}{2} = 4$.

MEAN, GEOMETRICAL, is the square root of the rectangle or product of the two extremes, thus; $\sqrt{1 \times 9} = 3$; $\sqrt{3 \times 12} = 6$. The third and two mean proportionals between two extremes multiplied each extreme by the square of the other; then extract the cube

root of the result, and the three terms will be in geometrical proportion. Thus, if 1 and 9 be the extremes, the mean will be 3, and the two mean proportionals sought.

HARMONICAL MEAN, is double the fourth proportional to the two extremes themselves a and b. Or it is the reciprocal of the arithmetical mean between the reciprocals of the given extremes.

MEASURE, among Botanists. In describing the parts of plants, Tournefort introduced a geometrical scale, which many of his followers have retained. They measured every part of the plant; and the essence of the description consisted in an accurate measurement of the whole. As the parts of plants, however, are liable to variation in no circumstance so much as that of dimension, Linnaeus very rarely admits any other measurement than that arising from the respective length and breadth of the parts compared together. In cases that require actual measurement, the same author recommends, in lieu of Tournefort's artificial scale, the following natural scale of the human body, the sum of the extremes, and which he thinks is much more convenient, and equally accurate. The scale in question consists of 11 degrees, which are as follows: 1. A man's breadth, or the diameter of a half (capitulum). 2. A line (linea), the breadth of the greatest or white appearance at the root of the finger, (not thumb, measured from the skin towards the body of the nail; a line is equal to 12 hairbreadths, and is the 12th part of a Parisian inch). 3. A nail (unguis), the length of a finger nail; equal to six lines, or half a Parisian inch. 4. A thumb (pollex), the length of the first or innermost joint of the thumb; equal to a Parisian inch. 5. A palm (palmas), the breadth of the palm exclusive of the thumb; equal to three Parisian inches. 6. A span (epithema), the distance between the extremity of the thumb and that of the first finger when extended; equal to seven Parisian inches. 7. A great span (dactylus), the distance between the extremity of the thumb and that of the little finger when extended, equal to nine inches. 8. A foot (pes), measuring from the elbow to the back of the thumb; equal to 12 Parisian inches. 9. A cubit (cubitus), from the elbow to the extremity of the middle finger, equal to 17 inches. 10. An arm length (brachium), from the armpit to the extremity of the middle finger, equal to 24 Parisian inches, or two feet. 11. A fathom (organa), the measure of the human stature; the distance between the extremity of the two middle fingers, when the arms are extended; equal, where greatest, to six feet.

MEASURE OF AN ANGLE, is the arch described from the vertex in any place between its legs. Hence angles are distinguished by the ratio of the arches; starting from the vertex between the legs to the periphery. Angles when so distinguished by these arches, and the arches are distinguished by their ratio to the periphery. Thus an angle is said to be double of another as the vertex in the said arch.

MEASURE OF A SOLID, is a cube whose side is an inch, a foot, or a yard, or any other determinate length. In geometry, it is a cubic perch, divided into cubic feet, digits, &c.

MEASURE OF VELOCITY, in Mechanics, is the space passed over by a moving body in a given time. To measure a velocity therefore, the space must be divided into as many equal parts as the time is conceived to be divided into; the quantity of space answering to each part of time is the measure of the velocity.

MEASURE OF FORCE FOR PERFECTING METAL AND OTHER SUBSTANCES. The measure of the force necessary to punch a hole through a plate of metal or other substance, must be an interesting subject to scientific readers. We shall therefore here insert the result of some of Mr. Bevan's experiments made on that subject. A good cylindrical steel punch was made, and fitted to a guide or director, so as to move correctly to a cylindrical hole in a steel plate connected with the guide; with this instrument the artist was able to force cylinders of metal very uniformly, and with little or no but to the hole, both by simple pressure and by percussion. The results of some experiments made on the force of simple pressure, to make a hole through a metal plate of one-eighth of an inch in thickness, and one-fourth of an inch in diameter, are as follow:—Plate iron, 3900 lbs.; cast-iron, 3800 lbs.; hammered brass, 3800 lbs.; copper,

2900 lbs. The following are the results from the same machine, on specimens of wood in the direction of the grain, of the same thickness and diameter.—Christiania deal, 135 lbs.; mahogany, 120 lbs.; dry box wood, 356 lbs.; beech, 204 lbs.; ash, 197 lbs.; oak 156 lbs.; elm, 122 lbs.

Measure, in a legal and commercial sense, denotes a certain quantity or proportion of any thing, bought, sold, valued, or the like. On the 1st of May, 1825, a total alteration took place in the weights and measures hitherto used in Great Britain.

The Regulation of the Imperial System.—Take a pendulum which will vibrate seconds in London, on a level of the sea, in a vacuum; divide all that part thereof, which lies between the axis of suspension and the centre of oscillation into 301393 equal parts; then will ten thousand of those parts be an imperial inch, twelve thereof make a foot, and thirty-six thereof make a yard.

The Standard Yard is, "that distance between the centres of the two points in the gold studs in the straight brass rod, now in the custody of the clerk of the House of Commons, whereon the margin and figures of Standard Yard, 1760, are engraved, which is declared to be the genuine standard of the measure of length called a yard: and as the expansibility of the metal would cause some variation in the length of the rod in different degrees of temperature, the act determines that the brass rod in question shall be of the temperature of 62 deg. Fah. The measure is to be denominated the "Imperial Standard Yard," and to be the only standard whereby all other measures of length shall be computed. Thus the foot, the inch, the pole, the furlong, and the mile shall bear the same proportion to the Imperial Standard Yard as they have hitherto borne to the yard measure in general use."

The act also makes provision for the restoration of the standard yard, in case of loss, destruction, or defacement, by a reference to an *invariable natural standard*, which is to be that proportion which the yard bears to the length of a pendulum vibrating seconds of time in the latitude of London, in a vacuum at the level of the sea, which is found to be as 36 inches (the yard) to 39,1393 (the pendulum); thus a sure means is established to supply the loss which might by possibility occur.

Take a cubic inch of distilled water, at 62° of temperature, by Fahrenheit's thermometer, let this be weighed by any weight, and let such weight be divided into 262458 equal parts, then will one thousand of such parts be a troy grain; and seven thousand of those grains will be a pound avoirdupois, the operation having been performed in air. Ten pounds such as those mentioned of distilled water, at 62° of temperature, will be a gallon, which gallon will contain two hundred and seventy-seven cubic inches, and two hundred and seventy-four one thousandth parts of another cubic inch.

The Standard Pound is determined to be that standard pound troy weight made in the year 1758, in the custody of the clerk of the House of Commons; such weight is to be denominated the "Imperial Standard Troy Pound;" and after the first of May, 1825, it is to be "the only standard measure of weight from which all other weights shall be derived, computed, and ascertained and that one twelfth part of the said troy pound shall be an ounce, and one twentieth part of such ounce shall be a pennyweight, and that one twenty-fourth part of such pennyweight shall be a grain; so that 5760 such grains shall be a pound troy, and 7000 such grains shall be declared to be a pound avoirdupois, and one sixteenth part of the said pound avoirdupois shall be an ounce avoirdupois, and one sixteenth part of such ounce shall be a drachm."

If the standard pound shall be lost, destroyed, or defaced, the act directs that it shall be recovered by reference to the weight of a cubic inch of water: it having been ascertained that a cubic inch of distilled water, weighed in air by brass weights at the temperature of 62 deg. Fah. and the barometer at 30 inches, is equal to 252.458 grains, and as the standard troy pound contains 5760 such grains, it is therefore established that the original standard pound may be at any time recovered by making another weight to bear the proportion just mentioned to a cubic inch of water.

The Standard Gallon is determined by the act to be such measure as shall contain ten pounds avoirdupois of distilled water, weighed in air, at the temperature of 62 deg. Fah. and

the barometer at 30 inches, and such measure is declared to be the "Imperial Standard Gallon, and shall be the unit and only standard measure of capacity to be used, as well for wine, beer, ale, spirits, and all sorts of liquids, as for dry goods not measured by heaped measure; and that all other measures shall be taken in parts or multiples of the said imperial standard gallon—the quart being the fourth part of such gallon, and the pint one-eighth part—two such gallons making a peck, eight such gallons a bushel, and eight such bushels a quarter of corn, or other dry goods, not measured by heaped measure.

The standard for heaped Measure, for such things as are commonly sold by heaped measure, such as coal, coke, lime, fish, potatoes, fruit, &c. shall be "the aforesaid bushel, containing eighty pounds avoirdupois of water, as aforesaid, the same being made round with a plane and even bottom, and being 19½ inches from outside to outside;" and goods thus sold by heaped measure, shall be heaped "in the form of a cone, such cone to be of the height of at least six inches, the outside of the bushel to be the extremity of the base of such cone;" three such bushels shall be a sack, and twelve such sacks shall be a chaldron.

Stricken Measure. The last mentioned goods may be sold either by the heaped measure, or by the standard weight as before mentioned; but all other kind of goods not usually sold by heaped measure, which may be sold or agreed for by measure, the same standard measure shall be used, but it shall not be heaped, but stricken with a round stick, or roller, straight, and of the same diameter from end to end.

N. B. Copies and models of the standard of length, weight, and measure, are to be made and verified under the direction of the Treasury, and every county to be supplied with them for reference whenever required; and after the first of May, 1825, all contracts for sale, &c. by weight or measure shall relate to the standard, unless the contrary is specified. Existing weights and measures may be used, being marked so as to show the proportion they have to the standard measures and weights. Tables of equalization of the weights to be made by the Treasury. Tables also for the customs and excise, by which the duties will be altered so as to make them equal to what they are at present, in consequence of the alterations in the weights and measures. See WEIGHTS, &c.

The following extracts from the bill for ascertaining and establishing Uniformity of Weights and Measures, will explain this subject fully:—"Whereas it is necessary, for the security of commerce, and for the good of the community, that weights and measures should be just and uniform; and whereas, notwithstanding it is provided by the Great Charter, that there shall be but one measure and one weight throughout the realm; and, by the treaty of union between England and Scotland, that the same weights and measures should be used throughout Great Britain as were then established in England, yet different weights and measures, some larger and some less, are still in use in various places throughout the united kingdom of Great Britain and Ireland, and the true measure of the present standard is not verily known, which is the cause of great confusion and of manifest frauds; for the remedy and prevention of those evils for the future, and to the end that certain standards of weights and measures should be established throughout the united kingdom of Great Britain and Ireland:

"Be it therefore enacted by the king's most excellent majesty, by and with the consent of the lords spiritual and temporal, and Commons, in this present parliament assembled, and by the authority of the same, That a cubic inch of distilled water in a vacuum weighed by brass weights, also in a vacuum at the temperature of sixty-two degrees of Fahrenheit's thermometer, is equal to two hundred and fifty-two grains and seven hundred and twenty-four one thousandth parts of a grain.

"And be it further enacted, That the standard measure of capacity, as well for liquid as for dry goods not measured by heaped measure, shall be the gallon containing ten pounds avoirdupois weight of distilled water, weighed in air, at the temperature of sixty-two degrees of Fahrenheit's thermometer, the barometer being at thirty inches, to be used as well for wine, beer, ale, spirits, and all sorts of liquids, as for dry goods not measured by heap measure; and eight such gallons shall be a bushel, and eight such bushels, a quarter of corn or other dry goods not measured by heaped measure."

"And be it further enacted, That the standard measure of capacity, for coals, culm, lime, fish, potatoes, or fruit, and all other goods and things commonly sold by heaped measure, shall be the aforesaid bushel, containing eighty pounds avoirdupois of water as aforesaid, the same being made round with a plane and even bottom, and being nineteen inches and a half from outside to outside of such standard measure as aforesaid.

"And be it further enacted, That all contracts, bargains, sales, and dealings, which shall be made or had within any part of the united kingdom of Great Britain and Ireland, for any work to be done, or for any goods, wares, merchandise, or other thing to be sold, delivered, done, or agreed for, by weight or measure, where no special agreement shall be made to the contrary, shall be deemed, taken, and construed to be made and had according to the weights and standard measures ascertained by this act; and in all cases where any special agreement shall be made, with reference to any weight or measure established by local custom, the ratio or proportion which every such local weight or measure shall bear to any of the said standard weights or measures, shall be expressly declared and specified in such agreement, or otherwise such agreement shall be null and void.

"And whereas it is expedient that persons should be allowed to use the several weights and measures which they may have in their possession, although such weights and measures may not be in conformity with the standard weights and measures established by this act; be it therefore enacted, That it shall and may be lawful for any person or persons to buy and sell goods and merchandise by any weights or measures established either by local custom, or founded on special agreement; provided always, that in order that the ratio or proportion which all such measures and weights shall bear to the standard weights and measures established by this act, shall be and become a matter of common notoriety, the ratio or proportion which all such customary measures and weights shall bear to the said standard weights and measures, shall be painted or marked upon all such customary weights and measures respectively; and that nothing herein contained shall extend, or be construed to extend, to permit any maker of weights or measures, or any person or persons whomsoever, to make any weight or measure at any time after, except in conformity with the standard weights and measures established under the provisions of this act.

"And be it further enacted, That accurate tables shall be prepared and published, shewing the proportions between the weights and measures heretofore in use, as mentioned in such acquisitions, and the weights and measures hereby established; and after the publication of such tables, all future payments to be made shall be regulated according to such tables.

"And whereas the weights and measures by which the rates and duties of the customs and excise, and other his majesty's revenue, have been heretofore collected, are different from the weights and measures of the same denominations directed by this act to be universally used; and whereas the alteration of such weights and measures may, without due care had therein, greatly affect his majesty's revenue, and tend to the diminishing of the same; for the prevention thereof, be it therefore enacted, That, so soon as conveniently may be, accurate tables shall be prepared and published; in order that the several rates and duties of customs and excise, and other his majesty's revenue, may be adjusted and made payable according to the respective quantities of the legal standards directed by this act to be universally used; and that from and after the publication of such tables, the several rates and duties thereafter to be collected by any of the officers of his majesty's customs or excise, or other his majesty's revenue, shall be collected and taken according to the calculations in the tables to be prepared as aforesaid."

TABLE of the several Standard Measures.—ENGLISH.

Barley-measures		Long Measure.	
3	=	1 Inch	
36	=	12	= 1 Foot
108	=	36	= 3 = 1 Yard
504	=	108	= 10 1/2 = 1 Pole
2178	=	540	= 60 = 220 = 40 = 1 Furlong
17728	=	6912	= 1728 = 320 = 8 = 1 Mile

Also,

4	Inches	=	1 Hand
6	Feet	=	1 Fathom.
3	Miles	=	1 League.
60	Geographical Miles	=	1 Degree.
360	English Miles	=	1 Degree nearly.
360	Degrees, or 25000 Miles,	=	is equal to the Circumference of the Earth nearly.

Cloth Measure.

2 1/2	=	1 Nail
9	=	4 = 1 Quarter.
36	=	16 = 4 = 1 Yard.
27	=	12 = 3 = 1 Ell Flemish.
45	=	20 = 5 = 1 Ell English.
54	=	24 = 6 = 1 Ell French.

The French standard was formerly the aune or ell, containing 3 Paris feet, 7 inches, 3 lines, or 1 yard 2-sevenths English; the Paris foot royal exceeding the English by 68-thousandths parts. This ell is divided two ways, viz. into halves, thirds, sixths, and twelfths; and into quarters, half-quarters, and sixteenths.

The standard in Holland, Flanders, Sweden, a good part of Germany, many of which were formerly called the Hans-towns, as Dantzig and Hamburg, and at Geneva, Frankfurt, &c. is likewise the ell; but the ell in all these places differs from the Paris ell. In Holland it contains one Paris foot eleven lines, or four-sevenths of the Paris ell. The Flanders ell contains two feet, one inch, five lines, and half a line, or seven-twelfths of the Paris ell. The ell of Germany, Brabant, &c. is equal to that of Flanders.

The Italian measure is the braccio, brace, or fathom. This obtains in the states of Modena, Venice, Florence, Lucca, Milan, Mantua, Bologna, &c. but is of different lengths. At Venice it contains one Paris foot eleven inches three lines, or eight-fifths of the Paris ell. At Bologna, Modena, and Mantua, the brace is the same as at Venice. At Lucca it contains one Paris foot nine inches ten lines, or half a Paris ell. At Florence, it contains one foot nine inches four lines, or forty-nine hundredths of a Paris ell. At Milan, the brace for measuring of silks is one Paris foot seven inches four lines, or four-ninths of a Paris ell; that for woollen cloths is the same with the ell of Holland. Lastly, at Bergamo, the brace is one foot seven inches six lines, or five-ninths of a Paris ell. The usual measure at Naples, however, is the canna, containing six feet ten inches and two lines, or one Paris ell and fifteen-sevenths.

The Spanish measure is the vara or yard, in some places called the vara, containing seventeen twenty-fourths of the Paris ell. But the measure in Castile and Valencia is the pan, span, or palm; which is used, together with the canna, at Genoa. In Arragon, the vara is equal to a Paris ell and a half, or five feet five inches six lines.

The Portuguese measure is the cavedos, containing two feet eleven lines, or four-sevenths of a Paris ell; and the vara, an hundred and six whereof make an hundred Paris ells.

The Piedmontese measure is the ras, containing one Paris foot nine inches ten lines, or half a Paris ell. In Sicily, their measure is the canna, the same with that of Naples.

The Muscovy measures are the cubit, equal to one Paris foot four inches two lines; and the arsin, two whereof are equal to three cubits.

The Turkish and Levant measures are the pieq, containing two feet two inches and two lines, or three-fifths of the Paris ell. The Chinese measure, the cobre, ten whereof are equal to three Paris ells. In Persia, and some parts of the Indies, the guaze, whereof there are two kinds; the royal guaze, called also the guaze monkeler, containing two Paris feet ten inches eleven lines, or four-fifths of the Paris ell; and the shorter guaze, called simply guaze, only two-thirds of the former. At Goa and Ormus, the measure is the vara, the same with that of the Portuguese, having been introduced by them. In Pegu, and some other parts of the Indies, the cando or candi, equal to the ell of Venice. At Goa, and other parts, they use a larger cando, equal to seventeen Dutch ells; exceeding that of Babai

and Balsora by $\frac{1}{2}$ per cent. and the vara by $\frac{1}{4}$. In Siam, they use the ken, short of three Paris feet by one inch. The ken contains two soka, the sok two keubs, the keub twelve nious or inches, the nion to be equal to eight grains of rice, i. e. to about nine lines. At Cambodia, they use the baster; in Japan, the tatam; and the span on some of the coasts of Guibon.

Square Measure.

Inches	
144 =	1 Foot.
1296 =	9 = 1 Yard.
36204 =	272 $\frac{1}{2}$ = 30 $\frac{1}{2}$ = 1 Pole.
1568160 =	10890 = 1210 = 40 = 1 Road.
6272640 =	43560 = 4840 = 160 = 4 = 1 Acre.
Also, 6 $\frac{1}{2}$ Yards = 1 Pole.	
40 Poles = 1 Road.	
4 Roads = 1 Acre.	

Square, Superficial, or Land Measure.—English square measures are raised from the yard of 36 inches multiplied into itself, and thus producing 1296 square inches in the square yard; the divisions of this are square feet and inches; and the multiples, poles, roads, and acres. Because the length of a pole is $5\frac{1}{2}$ yards, the square of the same contains 30 $\frac{1}{2}$ square yards. A square mile contains 640 square acres. In measuring fens and woodlands, 18 feet are generally allowed to the pole, and 36 feet in forest land. A hide of land, frequently mentioned in the earlier part of the English history, contained about 160 arable acres; and five hides were esteemed a knight's fee. At the time of the Norman conquest, there were 243,000 hides in England.

Scotch square or land measure is regulated by the Scotch ell: 36 square ells = 1 fall, 40 falls = 1 rood, 4 roods = acre. The proportion between the Scotch and English acre, supposing the feet in both measures alike, is as 1660 to 1680, or nearly as 5 to 4. If the difference of the feet be regarded, the proportion is as 10,000 to 7800. The length of the chain for measuring land in Scotland is 28 ells, or 74 feet. A husband-land contains six acres of sock and seythe land, that is, of land that may be tilled with a plough or mown with a seythe; 13 acres of arable land make one ox-gang; and four ox-gangs make a poundland of old extent.

French square measures are regulated by 12 square lines in the inch square, 12 inches in the foot, 21 feet in the perch, and 106 perches in the arpent or acre.

Cubic Measure.

Inches.	
1728 =	1 Foot.
46656 =	27 = 1 Yard.

Wine Measure

Pints.	
2 =	1 Quart.
8 =	4 = 1 = 1 Gallon = 231 Cubic Inches.
336 =	168 = 42 = 1 Tierce.
504 =	252 = 63 = 1 $\frac{1}{2}$ = 1 Hogshead.
672 =	336 = 84 = 2 = 1 $\frac{1}{2}$ = 1 Puncheon.
1008 =	504 = 126 = 3 = 2 = 1 $\frac{1}{2}$ = 1 Pipe.
2016 =	1008 = 252 = 6 = 4 = 3 = 2 = 1 Tun
231 Cubic Inches = 1 Gallon.	
10 Gallons = 1 Anker.	
18 Ankers = 1 Runlet.	
31 $\frac{1}{2}$ Gallons = 1 Barrel.	

Ale and Beer Measure.

Pints.	
2 =	1 Quart.
8 =	4 = 1 Gallon.
72 =	36 = 9 = 1 Firkin.
144 =	72 = 18 = 2 = 1 Barrel.
288 =	144 = 36 = 4 = 2 = 1 Barrel.
432 =	216 = 54 = 6 = 3 = 1 $\frac{1}{2}$ = 1 Hogshead.
672 =	336 = 84 = 2 = 1 $\frac{1}{2}$ = 1 Puncheon.
1008 =	504 = 126 = 3 = 2 = 1 $\frac{1}{2}$ = 1 Butt.

The Ale Gallon contains 282 Cubic Inches.

Scotch Long Measure.

	Eng. Inches.
An Ell	= 37 $\frac{1}{2}$
A Fath	= 223 $\frac{1}{2}$
A Furlong	= 8028
A Mile	= 71424
A Link	= 8028
A Chain, or Short Road	= 8028
A Long Road	= 13302

Measure of Capacity.

	Eng. Cub. Inch.
A Gill	= 6402
A Mutchkin	= 2585
A Choppin	= 517
A Pint	= 1034
A Quart	= 2068
A Gallon	= 82728
A Hogshead	= 132357, or 16 Gallons.

Cubical Measures, or Measures of Capacity, for Liquids.—The English measures were originally raised from troy weight: it being enacted by several statutes, that eight pounds troy of wheat, gathered from the middle of the ear, and well dried, should weigh a gallon of wine measure, the divisions and multiples whereof were to form the other measures; at the same time it was also ordered, that there should be but one liquid measure in the kingdom; yet custom has prevailed, and there having been introduced a new weight, viz. the avoirdupois, we have now a second standard gallon adjusted thereto, and therefore exceeding the former in the proportion of the avoirdupois weight to troy weight. From this latter standard are raised two several measures, the one for ale, the other for beer. The sealed gallon at Guildhall, which is the standard for wines, spirits, oils, &c. was supposed to contain 231 cubic inches; and on this supposition the other measures raised therefrom will contain as in the foregoing table; yet by actual experiment, made in 1688, before the lord mayor and the commissioners of excise, this gallon was found to contain only 224 cubic inches; it was, however, agreed to continue the common supposed contents of 231 cubic inches; so that all computations stood on their own footing. Hence, as 12 is to 231, so is 4 $\frac{1}{2}$ to 231 $\frac{1}{2}$, the cubic inches in the ale gallon; but in effect the ale quart contained 70 $\frac{1}{2}$ cubic inches, on which principle the ale and beer gallon will be 282 cubic inches. The several divisions and multiples of these measures, and their proportions, are exhibited in the foregoing tables. The barrel for ale in London is 32 gallons, and the barrel for beer 36 gallons. In all other places of England, the barrel, both for ale and beer, was wont to be 34 gallons.

Scotch liquid measure is founded on the pint. The Scotch pint was formerly regulated by a standard jug of cast metal, the custody of which was committed to the borough of Stirling. This jug was supposed to contain 106 cubic inches; and though, after several careful trials, it has been found to contain only about 103 $\frac{1}{2}$ inches; yet, in compliance with established custom, founded on that opinion, the pint stoops are still regulated to contain 105 inches, and the customary ale measures are about $\frac{1}{4}$ above that standard. It was enacted by James I. of Scotland, that the pint should contain 41 ounces troy weight of the clear water of Tay, and by James VI. that it should contain 55 Scots troy ounces of the clear water of Leith. This affords another method of regulating the pint, and also ascertaining the ancient standard of the troy weight. As the water of Tay and Leith is alike, the troy weight must have been to the Scots troy weight as 55 to 41, and therefore the pound troy must have contained about 21 $\frac{1}{2}$ ounces Scots troy.

4 gills	= 1 mutchkin.	2 pints	= 1 quart.
2 mutchkins	= 1 chopin.	4 quarts	= 1 gallon.
2 chopins	= 1 pint.		

The Scotch quart contains 210 inches, and is therefore about $\frac{1}{4}$ less than the English wine gallon, and about $\frac{1}{2}$ less than the ale gallon.

As to the liquid measures of foreign nations, it is to be 7 Y

observed, that their several vessels for wine, vinegar, &c. have also various denominations, according to their different sizes and the places wherein they are used. The wooders of Germany, for holding Rhenish and Moselle wines, are different from their gauges, some containing 14 muids of Amsterdam measure, and others more or less. The aune is reckoned at Amsterdam for 8 steekans, or 20 verges, or for $\frac{1}{2}$ of a tun of 2 pipes, or 4 barrels, of French or Bourdeaux, which at this latter place is called *trigon*, because three of them make a pipe or two barrels, and six the said ton. The steekan is 16 mingles, or 32 pints; and the verge is, in respect of the said Rhenish and Moselle, and some other sorts of wine, 8 mingles, but in measuring brandy it consists of 64 mingles. The aune is divided into 4 ankers, and the anker into 2 steekans, or 32 mingles. The anker is taken sometimes for $\frac{1}{4}$ of a ton, or 4 barrels; on which footing the Bourdeaux barrel ought to contain at Amsterdam (when the cask is made according to the just gauge) 12½ steekans, or 200 mingles, wine and lees; or 12 steekans, or 192 mingles, *clack* wine; so that the Bourdeaux tun of wine contains 50 steekans, or 800 mingles, wine and lees, and 48 steekans, or 768 mingles, of pure wine. The barrels or poingons of Nantes, and other places on the river Loire, contain only 12 steekans, Amsterdam measure. The wine tun of Rochelle, Cogniac, Charente, and the isle of Rhé, differs very little from the tun of Bourdeaux, and consequently from the barrels and pipes. A tun of wine of Chalosse, Bayonne, and the neighbouring places, is reckoned 60 steekans, and the barrel 15, Amsterdam measure.

The old muid of Paris contains 450 quarts or 200 pints, wine and lees, or 200 pints clear wine, of which muids three make a ton.

The butts or pipes from Cadix, Malaga, Alicante, Benecarlo, Balce, and Mataro, and from the Canaries, Lisbon, Oporto, and Fayal, are very different in their gauges, though in all shipments they are all reckoned two to the tun.

Vinegar is measured in the same manner as wine, but the measures for brandies are different; these spirits from France, Spain, Portugal, &c. are generally shipped in large casks called pipes, butts, and pieces, according to the places from whence they are imported, &c. In France, brandy is shipped in casks called pieces at Bourdeaux, and pipes at Rochelle, Cogniac, the isle of Rhé, and other neighbouring places, which contain some more and some less, even from 50 to 90 *Amsterdam verges* or *veertels*, according to the capacity of the vessels, and the places they come from.

Dry Measure.

8	=	1 Gallon.
16	=	2
64	=	8 = 4 = 1 Bushel.
256	=	32 = 16 = 4 = 1 Quarter.
512	=	64 = 32 = 8 = 2 = 1 Quarter.
2560	=	320 = 160 = 80 = 40 = 20 = 10 = 5 = 1 Wey.
6144	=	610 = 320 = 160 = 80 = 40 = 20 = 10 = 5 = 1 Ane.
2048	=	Cubic Inches = 1 Gallon.
36	=	Bushels = 1 Chaldron of Coals.

Measure of Capacity for Things Dry. was the Winchester gallon heretofore, as for corn, salt, coals, and other dry goods, in England. The gallon contains 272½ cubic inches. The bushel is 2 gallons, or 545 inches. A cylindrical vessel, 18½ inch diameter, and 8 inch deep, is appointed to be used as a bushel in levying the malt tax. A vessel of these dimensions is rather less than the Winchester bushel of 2 gallons, for it contains only 510 inches, though probably there was no difference intended. The denominations of dry measure commonly used, are given in the first of the subjoined tables. Four quarters of each make a chaldron, five quarters make a wey or load, and 16 quarters make a ton. In measuring sea coal, five pecks make a bushel, nine bushels make a quarter or salt, four quarters make a chaldron, and 21 chaldrons make a score.

40 feet hewn timber make a load.

50 feet hewn timber make a load.

32 gallons make a herring barrel.

12 gallons make a herring barrel; or not add any more, as the above is a measure of capacity, and not of weight.

Scotch dry measure. There was formerly only one measure of capacity in Scotland, and some commodities were heaped, others stratified, or measured exactly to the capacity of the standard. The method of heaping was afterwards forbidden as unequal, and a larger measure appointed for such commodities as that custom had been extended to. The wheat *stiot*, used also for rye, pease, beans, salt, and grass seeds, contains 21 pints 1 mitchkin, measured by the Stirling jug. The barley *stiot*, used also for oats, malt, and potting, contains 21 pints. A different method of regulating the *stiot* was appointed from the dimensions of a cylindrical vessel. The diameter for both measures was fixed at 7½ inches, the depth 7 inches for the wheat *stiot*, and 13½ for the barley *stiot*. A standard constructed by these measures is rather less than when regulated by the pint; and as it is difficult to make vessels exactly cylindrical, the regulation by the pint has prevailed, and the other method gone into disuse.

If the Stirling jug contains 103½ inches, the wheat *stiot* will contain 2100 inches, which is more than two per cent. larger than the legal bushel of England, and about one per cent. larger than the Winchester bushel; and the barley *stiot* will contain 3204 inches. The barley *stiot* is nearly equal to six legal malt bushels. In Shropshire, 17 pecks are reckoned to the boll; in Inverness shire, 18 pecks; in Ayrshire, the boll is the same as the English quarter. And the *stiot* in many places are larger than the Edinburgh standard.

French dry, are, the *litron*, bushel, muid, mine, septier, muid, and *ton*. The *litron* is divided into two denominations, and four quarter *litrons*, and contains 16 cubic inches of Paris. By ordonnance, the *litron* is to be three inches and a half high, and three inches 10 lines broad. The *litron* for sale is larger, and is divided into two halves, four quarters, eight decims, quarters, and 16 mespreilles. The French bushel is different in different jurisdictions. At Paris it is divided into demi bushels, each demi bushel into two quarts, the quart into two half-quarts, and the half-quart into two litrons, so that the bushel contains 16 litrons. By ordonnance the Paris bushel is 19½ high, 12½ inches two lines and a half high, and ten inches broad, or in diameter within-side. The *minot* consists of three bushels, the mine of 12 *minots* or six bushels, the *sepiere* of 12 *minots* or 36 bushels, and the muid of 12 *sepiers* or 432 bushels. The bushel of oats is estimated double that of any other grain, so that there go 24 bushels to make the *sepiere*, and 288 to make the muid. It is divided into four picotins, the picotin containing two quarts, or four litrons. The bushel for salt is divided into two half bushels, four quarters, eight half quarters, and 16 *minots*; four bushels make a muid, 16 a *sepiere*, and 192 a muid. The bushel for wood is divided into halves, quarters, and half-quarters. Eight bushels make the *minot*, 24 a *mine*, 20 *minots*, or 320 bushels, the *bidet*. For plaster, 18 bushels make a sack, and 36 sacks a muid. For lime, three bushels make a *minot*, and 48 *minots* a muid. The *minot* is by ordonnance to be 11 inches 9 lines high, and 14 inches 8 lines in diameter. The *minot* is composed of three bushels, or 18 *litrons*; four *minots* make a *sepiere*, and 48 a muid. The French mine is a real vessel, having estimation of several others. At Paris the mine contains six bushels, and 24 make the muid; at Rouen the mine is four bushels, and at Digges 18 *minots* make a Paris muid. The *sepiere* differs in different places: at Paris it contains two *minots*, or eight bushels, and 12 *sepiers* the muid. At Rouen the *sepiere* contains two *minots*, or 12 bushels. Twelve *sepiers* make a muid at Rouen as well as at Paris; but 12 of the latter are equal to 14 of the former. At Boulon the *sepiere* contains a *minot* and a half; three of which *minots* make the *sepiere* of Paris. The muid or may of Paris consists of 19 *sepiers*; and is divided into *minots*, *minots*, bushels, &c. That for oats is double that for other grain, i. e. contains twice the number of bushels. At Orleans the muid is divided into *minots*, but those *minots* only contain $\frac{1}{2}$ Paris *sepiers* and a half. In some places they

see the ton in *liens* of the *void*, particularly at Nantes, where it contains 10 *septiers* of 40 bushels each, and weighs between 2200 and 2250 pounds. Three of these tons make 28 Paris *septiers*. At Rochelle, &c., the ton contains 42 bushels, and weighs two per cent. less than that of Nantes. At Brest it contains 20 bushels, is equal to 10 Paris *septiers*, and weighs about 2140 pounds. See *Ton*.

Dutch, Swedish, Polish, Prussian, and Muscovite. In these places, they estimate their dry things on the foot of the *last*, *last*, or *last*, so called according to the various proportions of the people who use it. In Holland, the last is equal to 19 Paris *septiers*, or 38 Bourdeaux bushels, and weighs about 4500 pounds; the last they divide into 27 *quids*, and the *quid* into four *scheepels*. In Poland, the last is 40 Bourdeaux bushels, and weighs about 4800 Paris pounds. In Prussia, the last is 133 Paris *septiers*. In Sweden and Muscovy they measure by the great and little last; the first containing 12 barrels, and the second half as many.

In Muscovy, they likewise use the *cheffard*, which is different in various places; that of Archangel is equal to three Bourdeaux bushels.

Italian. At Venice, Leghorn, and Lucca, they estimate their dry things on the foot of the *staro* or *stato*; the *staro* of Leghorn weighs 54 pounds; 172 *staros* and seven-eighths are equal to the Amsterdam last. At Lucca, 119 *staros* make the last of Amsterdam. The Venetian *stato* weighs 128 Paris pounds; the *stato* is divided into four quarters. Thirty-five *staros* and six-fifths, or 140 quarters and four-fifths, make the last of Amsterdam. At Naples and other parts, they use the *tomolo* or *tomolo*, equal to one-third of the Paris *septier*. Thirty-six *tomoli* and a half make the *carro*, and a *carro* and a half, or 54 *tomoli*, make the last of Amsterdam. At Palermo, 16 *tomoli* make the *salma*, and four *monditi* the *tomolo*. Ten *salmas* and three-sevenths, or 171 *tomoli* and three-sevenths, make the last of Amsterdam.

Flendish. At Antwerp, &c., they measure by the *vierdel*; 24 and one-half whereof make 19 Paris *septiers*. At Hamburg, the *schepel*; 40 whereof make 19 Paris *septiers*.

Spanish and Portuguese. At Cadix, Bilboa, and St. Sebastian, they use the *fanega*; 23 whereof make the Nantes by Rochelle ton, or nine Paris *septiers* and a half; though the Bilboa *fanega* is somewhat larger, inasmuch that 24 *fanegas* make a Nantes ton. At Seville, &c., they use the *anagoras*, containing a little more than the Paris *min*; 36 *anagoras* make 19 Paris *septiers*. At Bayonne, &c., the *coucha*; 50 whereof are equal to nine Paris *septiers* and a half. At Lisbon, the *aliquior*, a very small measure, 240 whereof make 19 Paris *septiers*; 60 the Lisbon *muid*.

Note. An English Inch = 0.0254 Metres.

Measure of Capacity.

Eng. Cub. Inc.	Eng. Cub. Inc.
Millilitre	0.0108
Centilitre	0.1028
Decilitre	1.028
Litre	10.28

Solid Measure.

Eng. Cub. Feet.	Eng. Cub. Feet.
Decistère, for fire wood	3.517
Stère, a Cubic Metre	35.317
Decastère	353.17

It will be observed, that in this system it is only necessary to remember the metre, are, litre, and stère, all the others having certain relations to these, being equal to them taken 10, 100, 1000, &c. times, or divided by those numbers; and these are indicated in all cases by the preceding part of the word, the terminations in all being the same; that is, in each class of measures. Thus,

Deca, prefixed, denotes 10 times; Hecto, 100 times; Kilo, 1000 times; &c. On the other hand, deci, centi, milli, denotes the 10th part, 100th part, 1000th part, &c. So that metre is the element of long measures; are, of superficial measures; stère, that of solid measure; and litre, is the element of the measures of capacity; also, gramme is the element of all weights, being itself the weight of a cubic centimetre of distilled water.—The are is the square decametre. The litre, the cubic decimetre. The stère, the cubic metre. The metre itself, one ten-millionth part of the terrestrial arc intercepted between the equator and north pole, as determined by the actual measurement of degrees in different latitudes.

One need only cast an eye over this system of measures, to see at once the great advantages that it possesses over the complicated systems of any other country. It not only renders the system incomparably more simple for all the practical purposes of life, but it annihilates at once all those rules in arithmetic, classed under the terms compound addition, subtraction, multiplication, and division; reducing the whole of arithmetic to the first simple rules. A child, under this system of weights and measures, may learn every thing necessary for entering into the common concerns of the world in a month, as well and better than in a year under our complicated system. It is perhaps too much to expect that we shall ever forego our prejudices so far as to adopt this system of a rival nation. Yet it must be allowed to be of infinite importance to reduce all those incongruous and incomparable measures now in use, to one simple and uniform system, that should be understood by every one; and we should therefore be happy to find the subject taken up by the English parliament, being well worthy of its serious attention.

Table of the Proportion of Long Measures of different Nations to the English Foot, which, for the sake of comparison, is supposed to be divided into 1000 parts.

English foot	1000

Defective History Referred.

A French league is about	3 English miles.
A German mile	3 Duto.
A Dutch mile	3 Duto.
An Italian mile	3 Duto.
A Spanish league	3 Duto.
A Russian verst	3 Duto.

Standard of Measure. Various attempts have been made by different mathematicians to find a perpetual standard of measure, which might be referred to at any time and under any circumstances, supposing the standard in present use to be lost. The above metric system of the French is founded on this principle; the terrestrial arc, from the equator to the pole, being taken as the standard of universal comparison.

Measure. In Geometry, denotes any quantity assumed as one, or only to which the ratio of the other homogeneous or similar quantities is expressed.

Measure of Wood for Fire. Is usually the cord, four feet high, as many broad, and eight long; this is divided into two half cords, called the *ways*, and by the French *measures*. Both the pieces stack upright to bound them; or *ways*, as being supposed like a wagon load.

Measure for Horses. Is the hand, which by statute contains four inches.

Meat. Two Preparations. The Moors have an easy method of preparing meat without spices, and very little salt, to keep it good, and always ready for eating, for two or three years in the warmest climates. The meat thus prepared is called *salut*, and is made of beef, mutton, or camel's flesh. That chiefly of beef. It is first uniformly cut in long slices, well salted, and suffered to lie twenty-four hours in the pickle. It is then removed from those tubs into others filled with fresh water, where it remains for a fortnight. It is next taken out, and hung on cords by the sun to dry. When thus very dry and hard, it is cut into pieces three inches long, and thrown into a tub of children of holding oil and salt sufficient to cover it. When it is boiled, till it be very clear and red on cutting it, when it is again taken out, and set to drain. After this, it undergoes this process: it stands to boil, while jars are prepared for storing it, by the same kind of cutting upon it the uliquid in which it was boiled or fried; and as soon as it is thoroughly cold, the vessels are closely stopped. Preserved in this manner, it will remain hard, and keep good for two years: the saltiness is considered the best and most palatable. When it is brought to the table by the Moors, after having been larded or fried, seasoned either with garlic, or the juice of lemon, and is considered an excellent dish. Meat is also preserved by the pyramidal mode. - See Act.

MECHANICAL, an epithet applied to whatever relates to mechanics. Thus we say, mechanical powers, causes, &c. The mechanical philosophy is the same with what is otherwise called *corpuscular philosophy*, which explains the phenomena of nature, and the operations of corporeal things, on the principles of mechanics; viz. the motion, gravity, arrangement, disposition, greatness or smallness, of the parts which compose natural bodies. This manner of reasoning is much used in medicine; and, according to Dr. Quinoy, is the result of a thorough acquaintance with the structure of animal bodies: for considering an animal body as a composition out of the same matter from which all other bodies are formed, and to have all those properties which concern a physician's regard, only by virtue of its peculiar construction; it naturally leads a person to consider the *solid parts*, according to their figure, contexture, and use, either as wheels, pulleys, wedges, levers, screws, cords, cables, strainers, &c. For which purpose, continues he, it is frequently found helpful to design in diagrams, whatsoever of that kind is under consideration, as is customary in geometrical demonstrations.

Mechanics, in Mathematics, denotes a construction of some problem, by the assistance of instruments, as the duplication of the cube and quadrature of the circle, in contradistinction to that which is done in an accurate and geometrical manner.

Mechanical Curve, is a curve, according to Descartes, which cannot be defined by any algebraic equation, and so

stands contrary to the method of Newton, who considers curves as *arithmetical* and others as *mechanical* curves. The latter, and others, call these *mechanical* curves *transcendental*, and dissent from Descartes, in excluding them out of his series. Leibnitz found a new kind of transcendental equations, where these curves are defined; but they do not continue constantly the same in all points of the curve, as algebraic ones do. See *Transcendental*.

Mechanism, is the solution of a Problem, is either when the thing is shown by repeated trials, or when lines used to the solution are not only truly geometrical, or by geometrical construction.

Mechanics, that branch of natural mathematics, which considers matter and moving powers, their nature and laws, with their effect in machines. See *Mechanics*. The term is equally applied to the doctrine of equilibrium of powers, more properly called *statics*, and to that science which treats of the generation and communication of motions, which constitutes *dynamics*, or mechanics strictly so called. This science is divided by Newton into practical and rational mechanics, the former of which relates to the mechanical powers, viz. the lever, balance, wheel and axis, pulley, wedge, screw, inclined plane, and funicular machine; and the latter or rational mechanics, to the theory of motion; showing when the force or power is given, how to determine the motion that will result from it; and conversely, when the circumstances of the motion are given, how to trace the force or power from which they arise. Leibnitz, in his course of natural philosophy, connects mechanics with those other branches of natural science which unfold the general principles that conduct the events of the material world. The science of mechanics being then for its object the consideration of machines, their elements, principles of action, and methods of operation we may divide them into two classes: those that are general and such as are particular. To the former belong the consideration of force, and the engine of oblique action which when composed of connected cords has been named the *funicular machine*; to the latter belong the lever, the wheel and axis, the inclined plane and screw, the wedge, and the pulley, commonly called the simple mechanical powers.

Mechanics according to the ancient sense of the word, considers only the energy of *crassa*, or machine. The authors who have treated the subject of mechanics seem generally to have observed, that all machines derive their efficacy from a few simple forms and dispositions that may be given to the *organs*, which are interposed between the agent and the resistance to be overcome; and to those simple forms they have given the name of mechanical powers, simple powers, or *simple machines*. The practical uses of the several mechanical powers were undoubtedly known to the ancients, but they were almost wholly unacquainted with the theoretical principles of this science till a very late period; and it is therefore not a little surprising that the construction of machines, or the instruments of mechanics, should have been pursued with such industry, and carried by them to such perfection. Vitruvius, in his treatise on architecture, enumerates several ingenious machines, which had then been in use from time immemorial. We find, that for raising or transporting heavy bodies, they employed most of the means which are at present commonly used for that purpose, such as the crane, the inclined plane, the pulley, &c.; but with the theory or true principles of equilibrium they seem to have been unacquainted till the time of Archimedes. When, however, we consider the vast gigantic undertakings of the ancients, we cannot help believing that their genius supplied them with many engines of which we now know nothing, though we far surpass them in numerous methods of abridging human labour and the application of force. Yet from the time of Archimedes till the sixteenth century, the theory of mechanics remained in that prime of science left it. Stevinus a Fleming, Galileo, Torricelli, Descartes, Huygens, Wallis, Wren, Newton, Leibnitz, Dehautes, Duglied, Kell, Delaunoy, Lagrange, Awood, Prony, Pierson, Watt, Gregory, Young, &c. have, in succession, done the period to which we have alluded, explained and applied the principles of this civilizing science in a wonderful manner.

The *Lever*, which consists of an indestructible bar ABC , (see the Plate, fig. 20,) either straight or bent, resting on a point C , called the *Fulcrum*, the power being applied at the end A of

LEVERS

MECHANICAL POWERS.

PULLEYS

the arm A C, to raise a weight at the end B of the other arm C B. Throwing out of view the weight of the lever itself, and supposing it to be at first horizontal; let it shift into the proximate position A' C B'. The minute arcs A A' and B B' thus described may be regarded as tangents, and, consequently, while the power P descends vertically through the space A A', the weight W rises through the space B B'; wherefore the opposite momenta being equal, $P \times A A' = W \times B B'$, and $P : W :: B B' : A A' :: B C : A C$, or the power and weight are inversely as their distance from the fulcrum. Levers are usually distinguished into three kinds, according to the relative position of the power, the weight, and the fulcrum. 1. When the fulcrum D, (fig. 1,) lies between the power P and the weight W. This kind includes the crow and handspike, pincers, and scissors. The toothed hammer is only a bent lever of this kind. Its invention was in mythology ascribed to Neptune, his trident being only a three-pronged crow. The arm B C is commonly longer than A B, and consequently the weight W exceeds the power P. The number of times which the weight contains the power, is always called the *mechanical advantage* or *purchase*.

In making experiments with this machine, the shorter arm A B must be as much thicker than the longer arm B C as will be sufficient to balance it on the prop D. This supposed, let P represent a power whose weight or purchase is equal to 1 pound, and let the weight of W equal 12 pounds, then, if the power be twelve times as far from the fulcrum as the weight is, they will exactly counterpoise; and a small addition of purchase to the power P will force it down, and raise the weight W; and the velocity with which the power descends will be to the velocity with which the weight rises, as 12 to 1; that is, directly as their distances from the fulcrum, and, consequently, as the spaces through which they move. Hence, a man, who, by his natural strength, without the help of any machine, could support a hundred weight, will by the help of this lever be enabled to support twelve hundred. If the weight be less, or the power greater, the fulcrum may be placed so much farther from the weight; and then it can be raised to a proportionably greater height. For, universally, if the intensity of the weight multiplied into its distance from the fulcrum, be equal to the intensity of the power multiplied into its distance from the fulcrum, the power and weight will exactly balance each other; and a little addition to the power will raise the weight. Thus, in the present instance, the weight W is 12 pounds, and its distance from the fulcrum 1 inch; and 12 multiplied by 1 is 12; the power P is equal to 1 pound, and its distance from the prop is 12 inches, which multiplied by 1 is 12 again; and therefore there is an equilibrium between them. So, if a power equal to 2 pounds be applied at the distance of 6 inches from the fulcrum, it will just balance the weight W; for $6 \times 2 = 12$, as before; and a power equal to 3 pounds placed at 4 inches' distance, would be the same; for $3 \times 4 = 12$; and so on in proportion.

The *statera*, or Roman steelyard, explained under the word *BALANCE*, and used for finding the weights of different bodies by one single weight placed at different distances from the fulcrum or centre of motion D, (fig. 6.) is a lever of this kind. For, if a weight be hung at A, the extremity of the shorter arm D G is of such a weight as exactly to counterpoise the longer arm D X; if this arm be divided into any number of equal parts, each equal to O D, the single weight P will serve for weighing any thing as heavy as itself, or as many times heavier as there are divisions in the arm D X, or any quantity between its own weight and that quantity. As for example: If P = 1 pound, be placed at the first division 1 in the arm D X, it will balance 1 pound in the scale at W; if it be removed to the second division at 2, it will balance 2 pounds in the scale W; if to the third, 3 pounds; and so on to the end of the arm D X. If each of these integral divisions be subdivided into as many equal parts as a pound contains ounces, and the weight P be placed at any of these subdivisions, so as to counterpoise what is in the scale, the pounds and odd ounces therein will by that means be ascertained.

2. When the weight W lies between the fulcrum G and the power P, (fig. 2.) This kind includes the crow in its more general application, the baker's and druggist's knife, the com-

mon door, the wheel-harrow, nut-crackers, and oars. In this, as well as the former, the advantage gained is as the distance of the power to the distance of the weight from the fulcrum: for the respective velocities of the power and weights are in that proportion; and they will balance each other when the intensity of the power, multiplied by its distance, is equal to the intensity of the weight multiplied by its distance. Thus, if A B, be a lever on which the weight W of 6 pounds hangs at the distance of 1 inch from the prop G, and a power P, equal to the weight of 1 ounce, hangs at the end B, 6 inches from G, by the cord C D going over the fixed pulley E, the power will merely support the weight: and a small addition to the power will raise the weight 1 inch for every 6 inches that the power descends. This lever shows the reason why two men carrying a burden upon a stick between them, bear unequal shares of the burden in the inverse proportion of their distances from it. For the nearer either of them is to the burden, the greater share he bears of it: and if he goes directly under it, he bears the whole. So if one man be at G, and the other at B, having a pole or stick A B resting on their respective shoulders; if the burden be five times nearer G than A, the man G will bear five times as much as B. If the load G be only placed upon the pole P W, as in fig. 20, a vertical from the centre of gravity G, will in going up a hill divide the space unequally at C, and the lower person must therefore suffer a greater strain. Two horses of unequal strength may yet be yoked to draw equally, by a proportionate division of the bar. This is partly effected in the ordinary way, by attaching the perch to a short projection from the middle of the bar. To range a number of men along the arms of a pole, for the purpose of transporting heavy loads, is very unskilful, though frequently done in this country. Those who are nearest must evidently take the greatest share of the burden, while the remote bearers have not the means of exerting their strength. The method practised in the East is much preferable, the strain being successively subdivided by a system of levers crossing each other.

3. When the power P is applied (fig. 3) between the fulcrum E and the weight W. To this kind belong the sheep-shears. It has a mechanical disadvantage, but admits of a proportionally wider motion. The bones of animals are therefore levers generally of this sort, pulled by the moderate contraction of muscles inserted nearer their joints or centre of motion than the centre of gravity of the weight to be raised. That there may be a balance in this lever, between the power and the weight, the intensity of the power must exceed the intensity of the weight just as much as the distance of the weight from the prop exceeds the distance of the power. For example, 1 pound placed three times as far from the prop E as the power P acts at F, by the cord C going over the fixed pulley D, the power must be equal to 3 lbs. to support the weight of 1 lb. Upon the principle of this lever, we see men raise ladders against a wall, and also the wheels of a clock move, because their moving power acts upon them near the centre of motion by means of a small pinion which is the fulcrum.

The *Bent Lever*, differs in nothing from the first, except in being bent for the sake of convenience. A B C, fig. 4, is a lever of this sort, bent at C, which is its fulcrum or centre of motion. P is the power acting upon the longer arm A C at F, by means of the cord D E going over the pulley G; and W is a weight or resistance acting upon the end B of the shorter arm C B. If the power is to the weight as C B : C F, they are in equilibrium; for if W = 5 lbs. acting at the distance of 1 foot from the centre of motion C, and P = 1 lb. acting at F, 5 feet from the centre C, the power and weight will just balance each other.

The *Universal Lever*, is occasionally used for raising weights, but more commonly for dragging logs to the saw-pit. This is effected by annexing to the end of the short arm two claws, which work alternately in the teeth of a ratchet wheel. In fact, the wheel and pinion are but an extension of the lever.

One of the most ordinary and yet useful applications of the lever, is to weigh substances, or to compare their weights by means of a standard, as shewn in fig. 5, where the common balance, though less expeditious than the steelyard, as shewn in fig. 6, is yet capable of greater accuracy. As it has equal arms C E, D E, it requires a series of intermediate weights,

which are thrown into either scale A or B, and the whole is suspended on the pivot or fulcrum E. H is a mere hook by which to suspend the machine. For philosophical purposes, the easiest way is to reckon always by grains. The geometrical progression 1, 2, 4, 8, 16, 32, 64, &c. forms the simplest arrangement; but it will be found more convenient to follow the decimal division, and the successive sets of 1, 2, 3, and 4; 10, 20, 30, and 40; 100, 200, 300, and 400; 1000, 2000, 3000, and 4000, &c. would save much trouble in adding up the weights.

A *False Balance* has one arm somewhat longer than the other. But the fraud is easily detected, by interchanging the places of the weight, and the substance to be weighed; for the weight assigned will then be diminished, in the same proportion as it was before augmented. It perhaps deserves remark, that the true weight is rather less than half the sum of those opposite indications. Suppose BD (fig. 21) to represent the true weight, and let BD be to BA in the ratio of the arms of the fraudulent balance; having completed the semicircle, it is evident that AB will indicate the weight of the substance when placed in the scale of the longer arm, and BC its weight when suspended from the shorter arm. But BD is less than the radius, or the arithmetical mean between AB and BC. Since, from the property of the semicircle, BD is a mean proportional or geometrical mean between AB and BC, the true weight of any body might be discovered even by means of a false balance. Let it be weighed first in one scale, and then in the other; and, the results being multiplied together, the square root of their product will give the accurate value. Every correct balance must, therefore, have arms of precisely equal lengths, or have its fulcrum placed equally distant from the extreme points from which the scales are suspended. But the delicacy of the instrument depends on the proximity of its fulcrum to the straight line joining those two points. To preserve a stable equilibrium, however, it must occupy a position somewhat above that line. The beam should be strong and light, its preferable form consisting hence of two hollow cones: it should turn with a fine knife-edge upon a plate of agate, polished crystal, or hard steel; and the scales should likewise be hooked from sharp edges. The sensibility is further augmented, and the risk of injury obviated, by various other contrivances, some of which we have already noticed in treating upon this useful domestic machine.

The *Wheel and Axle*, (fig. 7,) is reckoned the next mechanical power, and it consists merely of a wheel AB attached to a small cylinder CD moving about the same centre; the power is applied to the circumference of the wheel, and the weight W to be raised has a cord K lapped about the cylinder. This instrument may hence be regarded as a continued lever. The power is, therefore, to the weight, as the radius of the axle is to that of the wheel; or, if the principle of virtual velocities be preferred, the power and weight are inversely as the circumferences of the wheel and of its axle. If the circumference of the wheel be eight times that of the axle, then a power $P = 1$ lb. hanging by the cord I, which laps over the wheel, will balance a weight $W = 8$ lbs. hanging by the rope K, which goes round the axle. If spokes S, S, S, or arms, be applied to the wheel, the circumference described by these must be considered as the circle of action. In this sort of machines it is requisite to have a ratchet wheel on the end of the axle C, with a catch to fall into its teeth; which will at any time support the weight, and keep it from descending, if the person who turns the handle should, through inadvertency or carelessness, quit his hold while the weight is raising. Thus, by this means, the danger is prevented which might otherwise happen by the running down of the weight when left at liberty.

As varieties of the same instrument, we may name the *Capstan* or *Windlass*, and the *Common Gin*. In the latter, the rope which draws up the weight is wound about a drum, with a long projecting arm, which a horse puts in motion by treading round a circular path. Of a similar nature is the crane, driven by men or cattle, walking within its circumference; but here the purchase is only in the ratio of the distance of the point of impulsion from a vertical through the centre of the wheel, to the radius of the axle. The wheel and axle may turn also on different centres, and have their circumferences connected in

mutual action, either by means of a belt or strap, or by the indentation of a system of cogs or teeth. This arrangement is usually called *Wheel and Pinion*. The wheel has sometimes its axle of a tapered or conical shape, which gives it a varying purchase. This construction is adopted in the fusee of a watch, and is likewise employed advantageously in raising minerals, by an uniform pull from very deep pits, the rope at its greatest length being coiled about the narrow end of the axle, and advancing towards the wide end as it shortens.

The *Double Capstan* is a very ingenious contrivance, originally brought from China, for augmenting in any degree the efficacy of the wheel and axle, without reducing its strength. It consists of two conjoined cylinders of nearly equal diameters, turning about the same axis, the weight being supported by the loop of a very long cord, of which one end uncoils

from the smaller cylinder, while the other end laps constantly about the larger cylinder, as represented in the annexed figure. The elevation of the weight at each revolution is therefore equal to half the difference between the two circumferences, and the effect of the arrangement is the same as if the cord sustaining the weight had been wound about a cylinder, which has a circumference merely equal to that quantity. The mechanical advantage of the instrument, combined with its pulley, is hence in the ratio of the diameter of the larger cylinder to half its excess above that of the smaller one. Nearly the same effect is procured, by employing a single conical axle; one part of the train of cord unrolling itself from the smaller end, while the other part is coiled up towards the larger end.

The *Pulley* consists either of one moveable pulley, or a system of pulleys; some in a block or case which is fixed, and others in a block which is moveable, and rises with the weight. For though a single pulley that only turns on its axis, and moves not out of its place, may serve to change the direction of the power, yet it can give no mechanical advantage thereto; but is only as the beam of a balance, whose arms are of equal length and weight. Thus A, fig. 8, is a single pulley, and if it support the equal weights P and W, the cord BB to which they are appended, is equally stretched throughout, and the pulley A sustains both the weights, or is drawn with a force equal to twice P. It is properly but another form of the balance.

In the pulley, fig. 8, No. 2, a power of one (P 1,) will sustain twice its weight, (W 2,) the cord BB being stretched with a power of 1, and the part from A to P with an equal power.

In a combination of three moveable pulleys, ABC, fig. 9, connected by three distinct cords, each fastened at one end to an immoveable block above, the power of the whole is discovered by supposing two such weights, P and W, suspended so as to keep the machine in equilibrio, and then beginning with the least weight or power P, and considering what force each separate pulley sustains. Thus if P be one pound, the cord which sustains it acts at its other end upon the fixed block above, and is consequently re-acted upon by a force equal to one pound; and the pulley A, as in fig. 8, is drawn with a force equal to two pounds. By tracing the second cord in the same manner, it will appear that the pulley B is drawn with twice the force of A, or four pounds; and C is drawn with twice the force of B, or 8 pounds. So that the purchase of this machine is such, that the weight W has 8 times the power of P.

The velocity of the weight to that of the power is (in a similar way of arguing) thus: if P descend 8 inches, A will ascend 4; B, 2; and C or W, 1 inch, so that the velocities are reciprocally as the power and weight.

Another combination of pulleys, whereof two, A and B, fig. 10, run in the fixed block X; and two others C and D, in a moveable block, which raise the weight W; by pulling the cord at P, which goes successively over the pulleys A, D, B, C, and

is fastened to the fixed blocks. The purchase of this machine is known by considering that the cord is usually stretched throughout by putting two such weights, P and W, as will counterpoise each other: for P is sustained by the single cord, and W by four folds of the same, viz. by the parts *a, s, u, k*; so that if P be one pound, W will be four pounds.

The velocity of the power is to that of the weight as four to one, for if P descend four inches, the parts of the cord at *k* will ascend towards *e* four inches, and all the other parts of the cord, from the pulley C., will equally follow each other, and C or W will ascend one inch towards *s*; or the four parts of the cord *a, s, u, k*, will each be shortened one inch.

In like manner may the purchase of any other combination of pulleys be determined: and it will always happen, that the *momenta* of the weight and power will be equal, as in other mechanical powers. That is, if any power will raise one pound with a certain velocity, the same power will raise two pounds with half that velocity, or one hundred pounds with one hundredth part of that velocity, &c. But as a system of pulleys has no great weight, and lies in a small compass, it is easily carried about; and can be applied, in a great many cases, for raising weights, where other engines cannot; but they have a great deal of friction on three accounts:—1. Because the diameters of their axes bear a very considerable proportion to their own diameters. 2. Because in working they are apt to rub against one another, or against the sides of the blocks. 3. Because of the stiffness of the ropes that pass over and under them.

The Inclined Plane is chiefly employed to facilitate excavations, and to raise the materials in buildings; and the advantage gained by it is as great as its length exceeds its perpendicular height. Let A B, fig. 11, be a plane parallel to the horizon, and C D a plane inclined to it; and suppose the whole length C D be three times as great as the perpendicular height G F. In this case the cylinder E will be supported upon the plane C D, and kept from rolling down upon it, by a power equal to a third part of the weight of the cylinder. Therefore, a weight may be rolled up this inclined plane with a third part of the power which would be sufficient to draw it up by the side of an upright wall. If the plane was four times as long as it is high, a fourth part of the power would be sufficient; and so on in proportion. Suppose a man has occasion to set a weight upon an eminence, and the weight is so great that he cannot lift it by his natural strength, he will take a long stout plank, or something equivalent thereto, and setting it sloping, will push the weight before him up the plank, to the place designed to set it in; and such plank, or other contrivance like it, is an inclined plane. Now it is evident that the shorter this inclined plane is, the steeper is the ascent; and the longer the plane is, the ascent must be the easier. It is plain also, that it is much easier to push a rolling weight E along a level A B, fig. 12, up a hill D C, fig. 11, that rises gently, than up a hill A B, fig. 13, which is very steep.

The force wherewith a rolling body descends upon an inclined plane, is to the force of its absolute gravity, by which it would descend perpendicularly in a free space, as the height of the plane is to its length. For suppose the plane A B, fig. 12, to be parallel to the horizon, the cylinder will keep at rest on any part of the plane where it is laid. If the plane be so elevated, that its perpendicular height from D, fig. 13, is equal to half its length A B, the cylinder C will roll down upon the plane with a force equal to half its weight; for it would require a power (acting in the direction of A B) equal to half its weight, to keep it from rolling. If the plane D B, fig. 14, be elevated, so as to be perpendicular to the horizon, the cylinder C would descend with its whole force of gravity, because the plane contributes nothing to its support or hinderance; and therefore it would require a power equal to its whole weight to keep it from descending. To the inclined plane may be reduced all hatchets, chisels, &c.

Of the Wedge.—The fifth mechanical power or machine is the wedge, which may be considered as two equally inclined planes D B F and C B F, joined together at their bases *e* E F O, fig. 15; then D C is the whole thickness of the wedge at its back A B C D where the power is applied; E F is the depth or height of the wedge; D F the length of one of its sides, equal to C F, the length of the other side; and O F is its sharp edge, which is

entered into the wood intended to be split, by the force of a hammer or mallet striking perpendicularly on its back. Thus, A B, fig. 16, is a wedge driven into the cleft C B D of the wood F G. When the wood does not cleave at any distance before the wedge, there will be an equilibrium between the power impelling the wedge downward, and the resistance of the wood acting against the two sides of the wedge; when the power is to the resistance as half the thickness of the wedge at its back is to the length of either of its sides: because the resistance then acts perpendicular to the sides of the wedges. But when the resistance on each side acts parallel to the back, the power that balances the resistances on both sides will be as the length of the whole back of the wedge is to double its perpendicular height. When the wood cleaves at any distance before the wedge, (as it generally does,) the power impelling the wedge will not be to the resistance of the wood as the length of the back of the wedge is to the length of both its sides, but as half the length of the back is to the length of either side of the cleft, estimated from the top or acting part of the wedge. For if we suppose the wedge to be lengthened down from the top C D, to the bottom of the cleft at E, the same proportion will hold; namely, that the power will be to the resistance as half the length of the back of the wedge is to the length of either of its sides: or, which amounts to the same thing, as the whole length of the back is to the length of both the sides.

The wedge is a mechanical power of singular efficacy, and the percussion by which its action is obtained, is precisely that force which we can with the greatest convenience almost indefinitely increase. By means of the wedge, the walls of houses may be propped, rocks split, and the heaviest ships raised up,—operations to which the lever, the wheel and axle, and the pulley, are either ill adapted, or entirely incompetent. To the wedge are referred the axe, the spade, chisels, needles, knives, punches, and, in short, all instruments which, beginning with edges or points, grow gradually thicker. A saw is a number of chisels fixed in a line; and a knife, if its edge be examined with a microscope, will be found to be only a fine saw.

Of the Screw.—The sixth and last mechanical power which we have to notice, is the screw. The screw, strictly speaking, consists of two parts, which work within each other. One of these parts, and which is always meant when the word screw is used alone, is a *solid* cylinder, on the circumference of which is cut a spiral groove;—specifically called an *outside* or *convex* screw. The other part is a *hollow* cylinder, or at least, whatever its external form may be, it contains a cylindrical hole, within which is cut a spiral groove corresponding to that of the convex screw, which can be turned within it, and the spiral projections of one lock into the spiral hollows of the other. For the sake of necessary contradistinction, this latter part is called an *inside*, a *concave*, or *socket* screw; when spoken of generally, without reference to any other use, is its principal one, of an indispensable companion to the convex screw; but when it consists of a small piece of metal, as for drawing tight bolts of any description, it is most commonly called a *nut*; and when it is of considerable size, as for a large press or vice, it is usually called a *box*. The *thread* of a screw is its spiral projection; the *pace* or *step* of a screw is the distance between the threads; and the groove or gorge is the hollow between the threads.

To obtain an idea of the nature of the screw, and of its affinity to the inclined plane, cut a piece of paper in the form of an inclined plane, or half wedge, as A B C, fig. 17, and then wrap it round a cylinder, fig. 18: the edge of this plane or paper will form a spiral round the cylinder, which will give the thread of the screw. A screw is seldom used without the application of a lever to assist in turning it: it then becomes a compound machine of great force, either in compressing the parts of bodies together, or in raising great weights. As the lever or winch must turn the cylinder once round before the weight or resistance can be moved from one spiral winding to another, or before the screw working in its box can rise or sink the distance between the threads, as from *a* to *b*, therefore as much as the circumference of the circle described by the lever is greater than the pace of the screw, or distance between the threads, so much does the force of the screw exceed the motive force. For example, suppose the pace or distance of the threads to be half an inch, and the length of the lever 12 inches,

the circle described by the extremity of the lever where the power acts, will be about 76 inches, or 152 half inches, consequently, 152 times as great as the distance between two contiguous threads; therefore if the intensity of the power at the end of the lever be equal to one pound, that single pound will balance 152 pounds acting against the screw. If as much additional force be exerted as is sufficient to overcome the friction, the 152 pounds may be raised; and the velocity of the power will be to the velocity of the weight as 152 to 1. Hence we may clearly perceive, that the longer the lever, and the nearer the threads to one another, so much the greater is the force of the screw. The friction of the screw is very great, but we are indebted to this circumstance for a peculiar advantage in the use of this machine, which will sustain a weight, or press upon a body against which it is driven, after the power is removed or ceases to act. To enumerate all the uses of the screw, would be impossible. Among other purposes, it is applied to great advantage for measuring or subdividing small spaces; when thus applied it is called a *micrometer*, which may be made to indicate on an index plate, a portion of a turn, advancing the screw less than the fifty-thousandth part of an inch.

The threads of screws are differently formed, according to the materials of which they are made, or the use for which they are intended. The threads of wooden screws are generally angular, that they may rest upon a broad base, and thereby have their strength increased to the utmost. Small screws, whatever material they are made of, are generally angular also, not only for the same reason as the wooden ones, but because the angular thread is the most easily made. The metal screws which are used for large presses, vices, &c. have generally a square thread, a form which gives great steadiness of motion. A thread of which the sides are parallel, and the top and bottom a little rounded, is perhaps the most perfect of all forms. In the common screw, to which the preceding observations are exclusively applicable, the threads are one continued spiral, from one end to the other; but where there are two or more separate spirals running up together, as in the worm of a jack, or the principal screw of a common printing press, the descent of the screw in a revolution will be proportionately increased; and therefore whatever be the number of the spirals, they must, in calculating the power, be measured and reckoned as one thread.

The Endless Screw.—A screw is sometimes cut on an axle, to serve as a pinion, and by working in the circumference of a wheel; it is then called an *endless screw*, because it may be turned perpetually without advancing or receding, that is, without any other motion than a rotatory one. The threads of this screw are of the square form, and fit exactly into the spaces between the teeth of a wheel, which teeth are cut obliquely, to answer the threads. When the endless screw has been turned once round, the wheel has only made a portion of a turn equal to the distance between one of its threads; that is, the wheel has moved one tooth; and therefore the number of its teeth is always the same as the number of the revolutions made by the screw before it once turned round.

The construction and mechanical advantage gained by this screw may be best illustrated by a figure; let the wheel C, fig. 19, have an endless screw *a* working in the teeth of the wheel D, which suppose to be 48 in number. It is plain, that for every time the wheel C and screw *a* are turned round by the winch A, the wheel D will be moved one tooth by the screw, and therefore, in 48 revolutions of the winch, the wheel D will be turned once round. Then, if the circumference of a circle, described by the handle of the winch A, be equal to the circumference of a groove *e* round the wheel D, the velocity of the handle will be 48 times as great as the velocity of any given point in the groove. Consequently, if a line G goes round the groove *e*, and has a weight of 48 pounds hung to it below the pedestal EF, a power equal to one pound at the handle will balance and support the weight. To prove this by experiment, let the circumferences of the grooves of the wheels C and D be equal to one another; and then if a weight A, of one pound, be suspended by a line going round the groove of the wheel C, it will balance a weight of 48 pounds hanging by the line G; and a small addition to the weight H, will cause it to descend, and so raise up the other weight.

If a line G, instead of going round the groove *e* of the wheel D, goes round its axle, 1, the power of the machine will be as much increased as the circumference of the groove *e* exceeds the circumference of the axle; which supposing it to be six times, then one pound at H will balance six times 48, or 288 pounds, hung to the line on the axle; and hence the power or advantage of this machine will be as 288 to 1. That is to say, a man, who by his natural strength could lift an hundred weight, will be able to raise 288 by this engine. The use of the endless screw affords a very ready means of greatly diminishing a rotatory motion, and accomplishes at once what would otherwise require the intervention of two or three wheels; and although it operates slowly by a sliding motion, it has not probably more friction than any of the less simple combinations which might be employed to effect the same object. It possesses the advantage too, of moving a wheel with much more steadiness than a pinion, when the workmanship of both is of equal quality. This circumstance is not so much regarded by mechanics as perhaps it ought, and therefore the endless screw is often not used when it would be advantageous. The principal restriction to the use of this screw is, its being so liable to wear when its motion is very rapid: a rapid motion, therefore, should not be assigned to it, unless it be made of hardened steel, when the objection will be less forcible.

The coining engine consists of a screw carrying ponderous arms. The impulsion accumulated by the swing produces a stroke similar to the concentrator of force; but the violence of the blow is softened, and the stock partly consumed, by the prolonged friction of the slanting grooves of the screw, by which the stamper advances to the die.

As the endless screw, working in the teeth of a wheel, has its energy multiplied by their number, it is evident that it may act at once on two ratchet wheels divided almost alike, the difference in breadth between the parallel teeth being the space of exertion. By such a contrivance, which also reckons the revolutions, the mechanical purchase might be carried to any extent.

The Concentrator of Force, an engine that exhibits in a striking manner the accumulation and transfer of impulsion

among bodies, may be regarded as, next to Atwood's ingenious machine, an important addition to illustrative philosophical apparatus, since it not only sheds a clear light on some abstruse parts of mechanical theory; but may with advantage be directed, in a variety of important cases, to the practice of the arts. The concentrator consists of a ponderous wheel, composed of a thin circle of iron, loaded at the circumference with a broad swelling ring of lead, and fixed to a strong steel axle. To this axle is likewise attached several short cylinders, of different diameters, the smallest formed of brass, and divided into two parts, that are capable of locking together at pleasure. The axle, placed in a horizontal position, moves upon gudgeons on the top of a high solid frame; and the machine may be set in motion by turning a winch, or by the descent of a small weight fastened to a silk line, which passes over a pulley, and is lapped round one of the barrels. The fig. represents one of the best models that has yet been used, the frame being five feet in

height; the wheel has about 18 pounds weight, and is 17 inches

in diameter, while the diameters of the successive barrels are only $\frac{1}{4}$, $\frac{1}{2}$ and 3 inches. The principal application of this engine is to raise from its platform any great weight. If 1 pound, for instance, in descending through thirty feet, gradually communicates its impression to the wheel, and, the instant it reaches the ground, the detached part of the brass barrel should lock, and catch hold of the loop of a cord holding half a hundred weight, or 56 pounds, this mass will be almost immediately lifted up near 6 inches, and there suspended. But what is remarkable, and appears at first sight paradoxical, the effect is precisely the same about whatever barrel the line be wound. The result is quite altered, when different descending weights are used, the elevation produced being always proportional to them. Thus, the descent of 3 and 4 pounds through 30 feet, will raise 56 pounds to nearly 1 and 2 feet.

It is not difficult to explain generally these effects. Let the descending power be very small in comparison with the weight of the ponderous wheel, and suppose its action at first to be exerted at the rim. This rim, in which is condensed the entire mass, will now describe a space equal to the measure of descent, and the whole power may be considered as inciting its revolution. Consequently the square of the velocity acquired by the wheel must be proportional to the descending power multiplied into the space through which it falls. When the accelerating force acts upon a barrel smaller than the wheel, the energy exerted at the rim is proportionally diminished, but the space described by it is augmented in the same ratio, and therefore the square of the velocity resulting from those combined causes will continue unaltered. The square of the velocity, or measure of impulsion, is extinguished by the efforts expended in raising the weight; wherefore the power multiplied into the quantity of descent is \equiv the weight \times into its corresponding ascent. Hence the power and the weight are inversely proportional to the spaces which they severally describe.

Leslie, who has very fully examined this matter, gives a very rigid formula in exemplification of this principle, from which he shows that the fall of 2 lbs. through 30 feet would lift 500 lbs. over 1 inch and a third part; and if the force be accumulated, the concentrator will prove sufficient to start the greatest load, or overcome the most powerful obstacle. Instead of raising great weights, the concentrator might be adapted to tear asunder thick wires or metallic rods. The power exerted will then be inversely as the spaces through which those rods stretch, before they suffer fracture. The effects will consequently be augmented, by shortening the lengths of the rods. To the bottom of the engine, screw a strong bar above 4 feet in height, and to this fasten rods from 6 inches to a foot long. If the limit of extension, which precedes the final disruption, were only half an inch, the power exerted, though produced by the descent of a single pound, would amount to about 1500 lb. A rigid and unyielding body is hence the most easily torn or broken. But the impetus accumulated by the concentrator may be wholly consumed, in merely stretching a very elastic substance of sufficient length. If a light contorted spring, for instance, be opposed to the rotation of the mass, it will, by its large though languid extension, gradually destroy the motive energy. A thick woollen cord, loosely plaited, and tied to a ring at the bottom of the machine, will produce a similar effect. A slender hempen string, which has little of a stretching quality, may still serve the same purpose, if it be taken of an adequate length. It is only required that half the final strain multiplied into the corresponding extension should be equal to the product of the falling weight by its quantity of descent. A tension of 60 lb., acting through a height of one foot, would be sufficient to muffle and extinguish the momentum of rotation generated by the descent of one pound through 30 feet. To produce this effect, therefore, it is only wanted to select such a length of cord as will extend one foot, by the application of a strain of 120 lbs. A more slender substance, if proportionally more stretching, would have the same effect. In either case, a weight exceeding the absolute tension, and attached to the end of the string, would not, during the moderated consumption of the shock, be stirred in the slightest degree from its place. The strength of a cord depends on its thickness, but the power to resist impul-

sion is determined by its elasticity and its length. This principle, which has been much overlooked, enters largely into the consideration of practical mechanics. Hence the practice of stemming a ship's way into a harbour by the friction of a long rope, the momentum being thus gradually spent. A short rope, firmly fastened to the pier head, so far from staying the vessel, would instantly snap. For the same reason, a ship riding at anchor is obliged to lengthen her cables. When these are composed of chains, the tension resulting from a diminution of curvature is precisely the same as if a contractile force had been exerted. It is perhaps a general error in civil architecture to aim at mere solidity. Lightness and elasticity combined will often resist the shocks of ages, while stiff and ponderous materials are crumbled into ruins.

If the barrels be of 2 and 3 inches radii, then will the time of generating the impulsion be compounded of the inverse ratio of the radius of the barrel, and the inverse subduplicate ratio of the falling body, with the direct subduplicate ratio of the space of descent; while the time of expanding this impulsion is inversely as the weight to be raised, and directly in the subduplicate ratio of the falling body and of its descent. Thus one pound having a line curled about the smallest barrel, will descend through 30 feet in $1\sqrt{18.30}$ seconds, or $4\frac{1}{2}$ ''; connected with the middle barrel it would descend in $23\frac{1}{2}$ ''; but applied to the largest barrel it would only require $16\frac{1}{2}$ '' . The succeeding act of lifting 112 lbs. will occupy five-sixths of a second. Also, the impulsion which required $46\frac{1}{2}$ '' to accumulate, exerts in ascension a strain of 1500 lbs., which is sufficient to tear a rod of metal asunder in less than the thirtieth part of a second; for the greater the weight to be raised, the more rapid is the act of ascension; and it is the same thing, whether an obstacle be overcome, or a disruption effected. The slowness with which this impulsive energy collects, is remarkably contrasted with the rapidity of its subsequent discharge. The greatest effects may be concentrated within such a portion of time as eludes the observation of the senses, and appears really instantaneous.

The Concentrator of force thus finely elucidates the acquisition and the transfer of impulsive energy. The same accumulated momentum produces diversified effects, according to the way in which it is disposed. It will raise a ponderous mass, tear asunder a solid body, or will expend all its action in merely stretching a substance of a very distensible quality. These different purposes are attained in the operations of the mechanical arts; but sound theory is yet required to guide and improve the practice. This engine, constructed on a large scale, might hence, with obvious advantage, be adopted as a most powerful auxiliary in various operations of art. Many situations occur which require an immense effort to be made on a sudden, and within a very limited space. This can be accomplished only by storing up, as it were, a magazine of force, which may be opened and discharged at some precise moment. Even moderate animal exertion, if applied during any considerable time, will communicate to the concentrator an impulsion sufficient to burst the firmest obstacles, and to lift, through a short space, the most enormous loads.

This engine involves likewise the theory of the *Fly* which is annexed to various machines, not to augment their power, but merely to equalize their motion. The variable molting forces are thus, by the intervention of a heavy wheel, blended together in creating one great momentum, which afterwards maintains a nearly uniform action. The use of the fly in mechanics hence resembles a reservoir, which collects the intermitting currents, and dispenses its water in a regular stream.

Though it is evident, from the foregoing principles, that any one of the mechanical powers is capable of overcoming the greatest possible resistance, in theory; yet, in practice, if used singly for producing very great effects, they would frequently be so unwieldy and unmanageable, as to render it impossible to apply them. For this reason, it is generally found more advantageous to combine them together; by which means the power is more easily applied, and many other advantages are obtained. Of the various machines which have been contrived to illustrate the simple mechanical powers, or to illustrate their effects, we select the following:—

<i>D. for D. in the Dictionary.</i>	
A French league is about 2 1/2 English miles.	
A German mile is about 3 1/2 English miles.	
A Dutch mile is about 3 1/2 English miles.	
An Italian mile is about 3 1/2 English miles.	
A Spanish league is about 3 1/2 English miles.	
A Russian verst is about 1/2 English mile.	

Standard of Measure. Various attempts have been made by different mathematicians to find a perpetual standard of measure, which might be referred to at any time and under any circumstances, supposing the standard in present use to be lost. The above metric system of the French is founded on this principle; the terrestrial arc, from the equator to the pole, being taken as the standard of universal comparison.

Measure, in Geometry, denotes any quantity assumed as one or unity, to which the value of the other homogeneous or similar quantities is expressed.

Musons of Wood for Firring, is usually the cord, four feet high; as many broad, and eight long; this is divided into two half cords, called the *ways*, and by the French *meubres*; both the pieces stack upright to bound them, or *royes*, as being supposed half a wagon load.

Meat for Horses, in the hand, which by statute contains four inches.

MEAT, in Preservation. The Moors have an easy method of preparing their meat, without spices, and very little salt, to keep it good, and always ready for eating, for two or three years in the warmest climates. The meat thus prepared is called *schalt*, and is made of beef, mutton, or carter's flesh, and chiefly of beef. It is first uniformly cut in long slices, well salted, and suffered to lie twenty-four hours in the pickle. It is then removed from those tubs into others filled with fresh water, where it remains for a night; it is next taken out, and hung on cords in the sun to dry. When thoroughly dry and hard, it is cut into pieces three inches long, and thrown into a pan of oil, or boiling oil, and not sufficient to cover it; when it is boiled, till it be very clear and red on cutting it, when it is again taken out, and set to drain. After having undergone this process, it stands to cool, while jars are prepared for storing it; at the same time pouring upon it the liquor in which it was boiled or fried; and as soon as it is thoroughly cold, the vessels are closely stopped. Preserved in this manner, it will remain hard, and keep good for 400 years: the hardest is considered the best and most palatable. When it is brought to the table by the Moors, after having been sliced or fried, seasoned either with garlic, or the juice of lemon, and is considered an excellent dish. Meat is also preserved by the pyroligneous acid. See *Acid*.

MECHANICAL, an epithet applied to whatever relates to mechanics: Thus we say, mechanical powers, causes, &c. The mechanical philosophy is the same with what is otherwise called *corporeal philosophy*, which explains the phenomena of nature, and the operations of corporeal things, on the principles of mechanics; viz. the motion, gravity, arrangement, disposition, greatness or smallness, of the parts which compose natural bodies. This manner of reasoning is much used in medicine; and, according to Dr. Quinoy, is the result of a thorough acquaintance with the structure of animal bodies: for considering an animal body as a composition out of the same matter from which all other bodies are formed, and to have all those properties which concern a physician's regard, only by virtue of its peculiar construction; it naturally leads a person to consider the several parts, according to their figure, contexture, and use, either as wheels, pulleys, wedges, levers, screws, cords, cables, strainers, &c. For which purpose, sometimes he is frequently found helpful to design in diagrams, whatsoever of that kind is under consideration, as is customary in geometrical demonstrations.

MECHANICAL, in Mathematics, denotes a construction of some problem, by the assistance of instruments, as the duplication of the cube and quadrature of the circle, in contradistinction to that which is done in an accurate and geometrical manner.

MECHANICAL CURVE, is a curve, according to Descartes, which cannot be defined by any singular equation; and so

stands distinguished from algebraic or geometrical curves. Leibnitz and others call these 'mechanical' curves *transcendentes*, and distinguish Descartes, in excluding them out of geometry. Leibnitz found a new kind of transcendental equations, where these curves are defined; but they do not express constantly the same in all points of the curve, as algebraic ones do. See *TRANSCEMPTUAL*.

Mechanical Solution of a Problem, is either when the thing is done by repeated trials, or when lines used in the solution are not only truly geometrical, or by original construction.

MECHANICS, that branch of practical mathematics, which considers motion and moving powers, their nature and laws, and their effect in machines. See *MACHINES*. The term is equally applied to the doctrine of equilibrium of powers, more properly called *statics*, and to that science which treats of the generation and continuation of motions, which constitutes *dynamics*, or mechanics strictly so called. This science is divided by Newton into practical and rational mechanics, the former of which relates to the mechanical powers, viz. the lever, balance, wheel and axis, pulley, wedge, screw, inclined plane, and funicular machine; and the latter, or rational mechanics, to the theory of motion; showing when the forces or powers are given, how to determine the motion that will result from them; and conversely, when the circumstances of the motion are given, how to trace the forces or powers from which they arise. Leslie, in his course of natural philosophy, incorporates mechanics with those other branches of natural science which unfold the general principles that connect the events of the material world. The science of mechanics finding themselves for its object the consideration of machines, their elements, principles of action, and methods of operation, we may divide them into two classes: those that are general, and such as are particular. To the former belong the consideration of force, and the engine of oblique action, which, when composed of connected cords, has been named the *funicular machine*; to the latter belong the lever, the wheel and axis, the inclined plane and screw, the wedge, and the pulley, commonly called the simple mechanical powers.

Mechanics according to the ancient sense of the word, considers only the efficacy of organs, or machines. The authors who have treated the subject of mechanics systematically, have observed, that all machines derive their efficacy from a few simple forms and dispositions that may be given to the organs, which are interposed between the agent and the resistance to be overcome; and to those simple forms they have given the name of mechanical powers, simple powers, or simple machines. The practical uses of the several mechanical powers were undoubtedly known to the ancients, but they were almost wholly unacquainted with the theoretical principles of this science till a very late period, and it is, therefore, not a little surprising that the construction of machines, or the instruments of mechanics, should have been pursued with such industry, and carried by them to such perfection. Vitruvius, in his tenth book, enumerates several ingenious machines, which had then been in use from time immemorial. We find, that for raising or transporting heavy bodies, they employed most of the means which are at present commonly used for that purpose, such as the crane, the inclined plane, the pulley, &c.; but with the theory or true principles of equilibrium they seem to have been unacquainted till the time of Archimedes. When, however, we consider the vast gigantic undertakings of the ancients, we cannot help believing that their genius supplied them with many engines of which we now know nothing; though we far surpass them in numerous methods of abridging human labour and the application of force. Yet from the time of Archimedes till the sixteenth century, the theory of mechanics remained as that prince of science left it. Stevius, a Fleming, Galileo, Torricelli, Descartes, Huygens, Wallis, Wren, Newton, Leibnitz, Dechales, Oughtred, Keil, Boscovich, Lagrange, Atwood, Prony, Emerson, Watt, Gregory, Young, &c. have, in succession, since the period to which we have alluded, explained and applied the principles of this civilizing science in a wonderful manner.

The *Lever*, which consists of an inflexible bar ABC, (see the Plate, p. 20.) either straight or bent, resting on a point C, called the *fulcrum*, the power being applied at the end A of

LEVERS

MECHANICAL POWERS.

PULLEYS

stairs raised, together with his own weight, 109 chiliogrammes to one chiliometre;—that a man weighing 160 pounds French, can ascend by stairs three feet French in a second, for the space of 15 or 20 seconds;—that a man cultivating the ground performs $\frac{1}{2}$ as much labour as a man ascending stairs, and that his quantity of action is equal to 328 pounds avoirdupois raised through the space of 3282 feet:—that a man with a winch does $\frac{1}{2}$ as much as by ascending stairs,—and that in a pile engine, a man by means of a rope drawn horizontally, raised for the space of five hours 65 $\frac{1}{2}$ pounds French through one foot French in a second. When men walk on a horizontal road, Coulomb found that the quantity of action was a maximum when they were loaded, and that this maximum quantity of action is to that which is exerted by a man loaded with 100.25 pounds avoirdupois as 7 to 4.—The weight which a man ought to carry, in order that the useful effect may be a maximum, is 165.3 pounds avoirdupois. When the workman, however, returns unloaded for a new burden, he must carry 200.7 pounds avoirdupois.

According to Dr. Robinson, a feeble old man raised seven cubic feet of water = 437.5 pounds avoirdupois, 11 $\frac{1}{2}$ feet high in one minute, for eight or ten hours a day, by walking backwards and forwards on a lever; and a young man weighing 135 pounds, and carrying 30 pounds, raised 9 $\frac{1}{2}$ cubic feet of water = 578.1 pounds avoirdupois, 11 $\frac{1}{2}$ feet high, for 10 hours a day, without being fatigued.

From the experiments of Mr. Buchanan, it appears that the forces exerted by a man pumping, acting at a winch, ringing, and rowing, are as the numbers 1742, 2856, 3983, 4005.

According to Desaguliers and Smeaton, the power of one horse is equal to the power of five men. Several French authors suppose a horse equal to seven men, while M. Schulze considers one horse as equivalent to 14 men.—Two horses, according to the experiment of Amontons, exerted a force of 150 pounds French, when yoked in a plough. According to Desaguliers, a horse is capable of drawing, with a force of 200 pounds, two miles and a half an hour, and of continuing this action eight hours in the day. When the force is 240 pounds he can work only six hours. It appears from Smeaton's reports, that by means of pumps a horse can raise 250 hogsheads of water, 10 feet high, in an hour.—The most disadvantageous way of employing the power of a horse is to make him carry a load up an inclined plane, for it was observed by De la Hire, that three men, with 100 pounds each, will go faster up the inclined plane than a horse with 300 pounds. When the horse walks on a good road, and is loaded with about two hundred weight, he may easily travel 25 miles in the space of seven or eight hours.

When a horse is employed in raising coals by means of a wheel and axle, and moves at the rate of about two miles an hour, Mr. Fenwick found that he could continue at work 12 hours each day, two and a half of which were spent in short intervals of rest, when he raised a load of 1000 pounds avoirdupois, with a velocity of 13 feet per minute;—and that he will exert a force of 75 pounds for nine hours and a half, when moving with the same velocity. Mr. Fenwick also found that 200 ale gallons of water delivered every minute on an overshot water-wheel 10 feet in diameter; that a common steam engine, with a cylinder eight inches in diameter, and an improved engine with a cylinder 6.12 inches in diameter, will do the work of one horse, that is, will raise a weight of 1000 pounds avoirdupois, through the height of 13 feet in a minute. It appears from Mr. Smeaton's experiments, that Dutch sails in their common position with a radius of 9 feet and a half, that Dutch sails in their best position with a radius of eight feet, and that his enlarged sails with a radius of seven feet, perform the same work as one man; or perform one-fifth part of the work done by a horse.

Before concluding, we must revert to a circumstance which we have already noticed briefly, respecting the most efficient mode of employing the power of that useful, but very much abused animal, the horse. That the line of draught is often in a direction injurious to the horse, and tending to diminish his power as a mover of mechanism, will be evident to any person who considers the form of his shoulders. At the place where the neck rises from the chest, (see fig. 9, plate 4.) the shoulder blades form the resting place of his collar or harness into a

slope, *ap*. This slope or inclination forms an angle with a perpendicular to the horizon, of about fourteen or fifteen degrees; and therefore the line of traction or draught should form the same angle with the horizon, because he will then pull perpendicularly to the shape of his shoulder, and all parts of that shoulder will be equally pressed by the collar. Besides, in overcoming obstacles, the advantage of this inclined direction is mechanically great. Call *a*, fig. 10, plate IV. a wheel, *b* an obstacle, *c* the axle of the wheel, *d* the spoke which sustains the weight. A line drawn from the nearest part of the horizontal line of draught *ek*, to the fulcrum or obstacle at *e*, will form the acting part of a lever *ge*; and another line *ed*, being drawn from the fulcrum *e* to the nearest part of the spoke *d*, will form the resisting part of the same lever. Now, as the acting and resisting arms of the lever are of equal lengths, the lever becomes a scale-beam, and draught in the line *gk* must be equal to the weight of the wheel and all that it sustains, besides the friction; for if *ged* be a crooked lever, a pull at *g* must be equal to all the weight supported by *d*. But when a horse draws agreeably to the shape of his shoulders in the line *ek*, the acting part of the lever *ke* is lengthened nearly one-fourth; so that if it would require a pull at *g* equal to four hundred weight, a power applied at *k* will draw the wheel over the obstacle *b* with three hundred weight. To those unacquainted with the principles of mechanics, this truth may be easily proved by an ordinary scale-beam. The horse himself, considered as a lever, has in this inclined draught a manifest advantage over his obstacles, in comparison of a horizontal draught, as may be seen by fig. 9. When the horse is yoked to a post, or has any great obstacle to overcome, he converts himself into a lever, making his hind feet the fulcrum, and the centre of gravity of his body to lean over it, at as great a distance as possible, by thrusting out his hind feet; by this means, acting both by his weight and muscular strength, and lengthening the acting part of the lever *ab*, he overcomes the difficulty more by his weight than by his muscular strength, for the muscles of the fore legs act upon the bones to so great a mechanical disadvantage, that though he exerts them with all his might, they serve, in great efforts, for little more than props to the fore part of his body. Hence we see the great use of heavy horses for draught. But the great mechanical use and advantage of the inclined line of draught may be more particularly seen, by calling the line *ab*, fig. 9, the acting part of the lever and the nearest approach from the fulcrum *b* to the inclined line of draught, (that is, *bc*) the resisting part of the lever: compare this with the resisting part of a lever touching the horizontal line of draught, (that is, *bd*.) and it will be found nearly double; in consequence, agreeably to the known properties of the lever, a weight at *g* would require double the exertion in the horse to remove it, that the same weight would require were it placed at *e*. Hence it is evident, that in economizing animal strength, single-horse carts are preferable to teams, because in a team, all but the shaft horse must draw horizontally, and consequently in a manner inconsistent with their structure, and the established laws of mechanics.

ON THE TEETH OF WHEELS.—When one wheel impels another, the impelling power will sometimes act with greater, and sometimes with less force, unless the teeth of one or both of the wheels be parts of a curve generated after the manner of an epicycloid, by the revolution of one circle along the convex or concave side of the other. When one wheel so impels another, then their motion is uniform. To illustrate this, and show the application of the cycloid and epicycloid, to give form to the teeth of wheels, let a circle B, proceed in a straight line on the plane CD, fig. 11, plate III. and at the same time revolve round its centre, till every part of the circumference has touched the plane, a point or pencil at *a*, which was lowest at the commencement of the motion, will have described the curve CED, which is called a *cycloid*, and is evidently compounded of a rectilinear and circular motion.

If a circle A, fig. 12, roll from *o* to *q*, on the convex circumference of another circle B, the point *o* will describe the curve *opq*, which is called an *exterior epicycloid*; and if the circle A were to roll on the concave circumference of the circle B, as from *r* to *s*, the point *r* would describe an *interior epicycloid*.

In all these cases, the circle by which the curve is obtained, is called the generating circle; and one wheel will not drive another with uniform velocity, unless the teeth of one or more of the wheels have their acting surfaces formed into a curve generated after the manner of an epicycloid. But it is not absolutely necessary that the teeth of one or both wheels be exactly epicycloids; for if the teeth of one of them be either circular or triangular, with plain sides, or like a triangle with its sides converging to the centre of the wheel, or of any other form, uniformity of force and motion will be attained, if the teeth of the other wheel have a figure which is compounded of that of an epicycloid and the figure of the teeth of the first wheel. From a variety of cases, we select such forms for the teeth as are best adapted to practice. There are three different ways in which the teeth of wheels may act upon one another; and each mode of action requires a different form for the teeth:—

1st. When the teeth of the wheel begin to act upon the leaves of the pinion just as they arrive at the line of centres; and their mutual action is carried on after they have passed this line. 2d. When the teeth of the wheel begin to act upon the leaves of the pinion before they arrive at the line of centres, and conduct them either to this line, or a very little beyond it. 3rd. When the teeth of the wheel begin to act upon the leaves of the pinion before they arrive at the line of centres, and continue to act after they have passed that line.

For the first, the acting faces of the leaves of the pinion should be parts of an interior epicycloid, generated by a circle of any diameter rolling upon the concave superficies of the pinion; and the acting surfaces of the teeth of the wheel should be portions of an exterior epicycloid, formed by the same generating circle rolling upon the convex superficies of the wheel. Now, it is demonstrable, that when one circle rolls within another whose diameter is double that of the rolling circle, the line generated by any point of the latter will be a straight line tending to the centre of the larger circle. If the generating circle, therefore, mentioned above, should be taken with its diameter equal to the radius of the pinion, and be made to roll upon the concave superficies of the pinion, it will generate a straight line tending to the pinion's centre, which will be the form of the acting faces of its leaves; and the teeth of the wheel will in this case be exterior epicycloids, formed by a generating circle, whose diameter is equal to the radius of the pinion, rolling upon the convex superficies of the wheel. This construction of the teeth of the wheel, and leaves of the pinion, is represented by fig. 13, plate III.; it is strongly recommended by De la Hire and Camus, and is perhaps the most advantageous, as it requires less trouble, and may be executed with greater accuracy, than if the leaves of the pinion had been curved as well as the teeth of the wheel.—The small wheel is the *pinion*; its teeth are called *leaves*; and the line joining their centres, is called the *line of centres*.

Lanterns or trundles, which consist of cylindrical staves fixed by both ends nearly at the circumferences of two equal circular boards, and which are so frequently substituted by millwrights for pinions, may often be adopted with great propriety, provided the teeth of the wheels working in them have a proper form. The following construction possesses the merit of diminishing the friction arising from the mutual action of the staves and the teeth, and is easily reduced to practice.

Let A, fig. 14, plate III., be the centre of the small wheel or trundle TCHQ, whose teeth are circular like ICR, having their centres in the circle PDEY. Upon B, the centre of the large wheel, at the distances BC, BD, describe the circles FCK, GDO; and with PDEY, as a generating circle, form the exterior epicycloid DNM, by rolling it upon the convex superficies of the circle GDO. The epicycloid DNM thus formed, would have been the proper form for the teeth of the large wheel GDO, had the circular teeth of the small wheel been infinitely small; but as their diameter must be considerable, the teeth of the wheel should have another form. In order to determine their proper figure, divide the epicycloid DNM into a number of equal parts, 1, 2, 3, 4, &c. and let these divisions be as numerous as possible. Then, upon the points 1, 2, 3, &c. as centres, with the distance DC equal to the radius of the circular tooth, describe portions of circles

similar to those in the figure; and the curve OPT, which touches these circles, and is parallel to the epicycloid DNM, will be the proper form for the teeth of the large wheel. In order that the teeth may not act upon each other till they reach the line of centres AB, the curve OP should not touch the circular tooth ICR till the point O has arrived at D. The tooth OP, therefore, will commence its action upon the circular tooth at the point I, where it is cut by the circle DRE. On this account, the part ICR of the cylindrical pin being superfluous, may be cut off, and the staves of the trundle will then be segments of circles similar to the shaded part of the figure.

The second mode of the mutual action of wheels and pinions above-mentioned is not so advantageous as the former, and therefore should, if possible, be avoided. It is evident, that when the tooth of the wheel acts upon the leaf of the pinion before they arrive at the line of centres, and quits the leaf when they reach this line, that the tooth works deeper and deeper between the leaves of the pinion the nearer it comes to the line of centres; hence friction arises, because the tooth does not, as before, *roll* upon the leaf, but *slides* upon it; and from the same cause, the pinion soon becomes foul, as the dust which lies upon the acting faces of the wheels is pushed into the hollows between them. One advantage, however, attends this mode; it allows us to make the teeth of the large wheel rectilinear, and thus renders the labour of the mechanic less, and the accuracy of his work greater, than if they had been of a curvilinear form. If the teeth, therefore, of the wheel are made rectilinear, having their surfaces directed to the wheel's centre, the acting surfaces of the leaves must be epicycloids formed by a generating circle, whose diameter is equal to the sum of the radius of the wheel, added to the depth of one of its teeth, rolling upon the circumference of the pinion. But if the teeth of the wheel and the leaves of the pinion are made curvilinear, the acting surfaces of the teeth of the wheel must be portions of an interior epicycloid formed by any generating circle rolling within the concave superficies of the large circle, and the acting surfaces of the pinion's leaves must be portions of an exterior epicycloid, produced by rolling the same generating circle upon the convex circumference of the pinion.

When the teeth of the large wheel are cylindrical spindles, either fixed or moveable upon their axis, an exterior epicycloid must be formed like DNM, in fig. 14, plate III., by a generating circle, whose radius is AC, rolling upon the convex circumference FCK; AC being in this case the diameter of the wheel, and FCK the circumference of the pinion. By means of this epicycloid, a curve OPT must be formed as before described, which will be the proper curvature for the acting surfaces of the leaves of the pinion, when the teeth of the wheel are cylindrical. In determining the relative diameter of the wheel and pinion for this mode of action, the radius of the wheel is reckoned from its centre to the extremity of its teeth, and the radius of the pinion from its centre to the bottom of its leaves.

The third way alluded to above, in which one wheel may drive another, namely, "when the teeth of the wheel begin to act upon the leaves of the pinion, before they arrive at the line of centres, and continue to act after they have passed that line," remains to be considered. It is represented by fig. 1, plate IV., and as it is a combination of the two first modes, it partakes both of their advantages and disadvantages. It is evident from the figure, that the portion *ea* of the tooth acts upon the part *bc* of the leaf till they reach the line of centres AB, and that the part *ed* of the tooth acts upon the portion *ba* of the leaf after they have passed that line. It follows, therefore, that the acting parts *ea* and *bc* must be formed according to the directions given for the first mode of action, and that the remaining parts *ed*, *ba*, must have that curvature which the second mode of action requires; consequently *ea* should be part of an interior epicycloid formed by any generating circle rolling on the concave circumference of the wheel, and the corresponding part *bc* of the leaf should be part of an exterior epicycloid formed by the same generating circle rolling upon *beo*, the convex circumference of the pinion; the remaining part *ed* of the tooth should be a portion of an exterior epicycloid, formed by any generating circle rolling upon

MECHANICAL

CONCRETE PAVING AND TROTTING BLOCKS

Iron Mill

eL , the convex superficies of the wheel; and the corresponding part ba of the leaf should be part of an interior epicycloid described by the same generating circle rolling along the concave side bEo of the pinion. But, as in practice, the production of this double curvature of the acting surfaces of the teeth would be exceedingly troublesome to the workman, who would probably never correctly accomplish his object, his labour may be abridged by making eh and ba radial lines, that is, eh a straight line tending to the centre of the wheel B , and ba likewise a straight line tending to the centre A , of the pinion.

The foregoing remarks apply to those cases in which the wheel drives the pinion. When the pinion drives the wheel, the form that has been directed to be given to the teeth of the wheel must be given to the leaves of the pinion, and that assigned to the leaves of the pinion must be given to the wheel.

Another method of forming the teeth, which has had many advocates, consists of making the acting faces of the teeth involutes of the wheel's circumference. Thus let AB , fig. 2, plate IV. be a portion of the wheel on which the tooth is to be fixed, and let Apm be a thread wrapped round its circumference, having a loop-hole at its extremity, a . In this loop-hole fix a pin e , with which describe the curve or involute, $abcdeh$, by unwrapping the thread gradually from the circumference Apm . The curve thus obtained will be the proper form for the teeth of a wheel whose diameter is AB . It is a form which admits of several teeth acting together, a circumstance attended with the advantage of diminishing the pressure upon any one tooth, so much as to make the wheels wear longer and more equally; and it possesses the merit of being more easily understood than the other methods directed to be observed. This last mode of forming the teeth of wheels is, however, only a modification of the general principle, and indeed an involute is sometimes reckoned among the exterior epicycloids. The propriety of this will be allowed, when it is considered that the involute $abcd$, &c. may be produced by an epicycloidal motion. Thus let on be a straight ruler, at whose extremity is fixed the pin w , and let the point of the pin be placed upon the point m of the circle; then by rolling the straight ruler upon the circular base, so that the point in which it touches the circle may move gradually from m towards B , the curve mn will be generated exactly similar to the involute abc , &c. obtained by the string.

Let the mechanic who wishes to have further directions for drawing epicycloids, take a piece of plain wood GH , fig. 3, plate IV., and fix upon it another piece of wood E , having its circumference mb of the same curvature as the circular base upon which the generating circle AB is to roll. When the generating circle is large, the shaded segment B will be sufficient. In any part of the circumference of this segment, fix a sharp pointed steel pin a , which ought to be tempered, that it may easily make a distinct mark; and it must be driven in sloping, so that the distance of its point from the centre of the circle may be equally exact to its radius. Fasten to the board GH , a piece of thin brass, or of tin plate, ab . Place the segment B in such a position that the point of the steel pin a may be upon the point b , and roll the segment toward G , so that the nail a may rise gradually, and the point of contact between the two circular segments advance towards m ; the curve ab , described upon the brass plate, will be an accurate exterior epicycloid. Remove, with a file, the part of the brass on the left hand of the epicycloid, and the remaining concave ab will be a pattern tooth, by means of which all the rest may easily be formed. When an interior epicycloid is required, the generating circle must revolve upon a concave instead of a convex base, as in the present instance. The cycloid, which is useful in forming the teeth of rack-work, is generated in precisely the same manner, with this difference only, that the base on which the generating circle rolls must be a straight line.

Perhaps no part of the mechanism of mill-work is executed with so little attention to theory as the teeth of wheels. Almost every millwright has his favourite construction, and it is seldom that the best methods are adopted. One of the many plans in ordinary use we shall here recite; from its being of tolerably easy application, and allowing much strength to the teeth, while it is somewhat free from friction in comparison with other practical methods. Let AB , fig. 4, plate IV., be two spur wheels of different diameters, of which the cogs are intended to work

into each other at half pitch. The dotted circular arcs GH , EF , touching each other between s and d , are the centre or pitch lines, from which the teeth are formed. If the teeth of both wheels are iron, as is generally the case in the first motions of work, those teeth are then made nearly both of a size at the pitch-line; but if the teeth of one be wood and the other iron, then the iron ones are made to have less pitch than the wooden ones, because they are then found to wear better. In the figure both are supposed to be of iron. Suppose the wheels to move from G toward H , and from E towards F , and that the sides of the teeth at bc , and de , are in contact; from b as a centre, with a radius equal to bp , describe the arcs pd , lm ; from d as a centre with the same radius, describe the arcs hi , fg , ck . Thus the same opening of the compasses, and a centre chosen where the wheels are in contact on the pitch lines, will mark the contour of the upper part of a tooth of one wheel, and the lower part of a corresponding tooth of the other wheel; and by taking several centres on the two pitch-lines, the various teeth may be formed. To prevent the cogs from *bottoming*, as the workmen call it, let the lower part, re , of one tooth be made rather longer than the upper part pd , of the other which is to play into it. The way in which cogs thus constructed will work into one another, may be understood by considering the motion of two of them, n and o for example; when they first come into contact, they will appear as the curve xPz ; when they arrive at Q , the same sides will appear as in the dotted lines there represented; and when the same arrive at RS , they are in contact on other middle points.

Of Wipers or Lifting Cogs.—It may be useful to notice here, that by means of notches called *wipers*, which project from the circumference of a wheel or axle, stampers, hammers, and other tools, are raised vertically and then suffered to fall.

Fig. 5, plate IV., represents portions of a stamper for bruising ore, beating hemp, &c. and of its shaft with lifting cogs. G is the vertical arm of the stamper, sliding, when in actual work, between rollers, or in a groove, to keep it steadily in its proper position; a is the horizontal arm of the stamper; H part of the axle, on which the wipers or lifting cogs EF are fixed; the dotted lines at A , shew the height to which the horizontal arm a , of the stamper, is elevated by each wiper. AB is a line corresponding with the arm of the stamper upon which the wipers first act; CD is the pitch-line of the axis, or the bottom of the curves of the wipers. The curved or acting faces of the wipers are involutes of a circle equal in radius to the axis CD , and obtained as already described in noting its application to the formation of the teeth of wheels, viz. by unwrapping from the circumference of the circle alluded to, a thread or cord b , in the loop-hole, at the extremity of which is a pencil or marking point, describing the curve as it approaches towards c . The arm of the stamper is flat at the part where the wiper acts upon it, and should be placed in a line with the centre of the shaft or axis, at the time the first wiper comes into contact with it.

Fig. 6, plate IV., exhibits the form of the wipers for a forge-hammer. The centre b , of the cylinder AB , in which the wipers are fixed, the flat part or tail-end of the hammer, where acted upon by the wipers, and the centre of the axis a of the hammer, must be in the same tight line. The proper curve for the wipers is an exterior epicycloid; formed by rolling upon the circumference of the circle at B , a circle of which the radius is equal to the distance from the centre of the axis a to the extremity of the tail of the hammer.

Description of a common Corn Mill.—The water wheel AB , fig. 7, plate IV., is generally from eighteen to twenty-four feet in diameter, reckoning from the outermost edge of any float-board at A , to that of the opposite one at B . The water striking on the floats of this wheel, drives it round, and gives motion to the mill. The wheel is fixed upon a very strong axis or shaft C , one end of which rests on D , and the other on E within the mill-house. On the shaft or axis C , and within the mill house, is a wheel F , about eight or nine feet in diameter, having cogs all round, which work in the upright staves or rounds of a trundle G . This trundle is fixed upon a strong iron axis, called the spindle, the lower end of which turns in a brass foot fixed at H , in a horizontal beam II , called the bridge-tree; and the upper end of the spindle turns in a wooden bush fixed into the nether mill-stone, which lies upon beams in the floor I . The

top of the spindle above the bush is square, and goes into a square hole in a strong iron cross, *abcd*, fig. 8, called the rynd, under which, and close to the bush, is a round piece of thick leather upon the spindle which it turns round at the same time it does the rynd. The rynd is let into grooves in the under surface of the upper or running mill-stone, which it turns round in the same time that the trundle *G* is turned round by the cog-wheel *F*. This mill-stone has a large hole quite through its middle, called the eye of the stone, through which the middle part of the rynd and upper end of the spindle may be seen; whilst the four ends of rynd lie below in their grooves.

One end of the bridge-tree *H*, which supports the spindle, rests upon the wall, and the other end is let into a beam called the brayer, *L M*. The brayer rests in a mortise at *L*, and the other end *M*, hangs by a strong iron rod *N*, which goes through the floor *I*, and has a screw and nut on its top at *O*; by the turning of this nut, the end *M* of the brayer is raised or depressed at pleasure, and consequently the bridge-tree and the upper mill-stone. By this means the upper mill-stone may be set as close to the under one, or raised as much above it, as may be necessary. It will of course be understood that the nearer the mill-stones are to each other, the finer the corn will be ground; and that, on the contrary, the further they are separated, the coarser it will be.

The upper mill-stone is enclosed in a round box, which nowhere touches it, and is about an inch distant from its edge all round. On the top of this box stands a frame for holding the hopper *P*, to which is hung the shoe *Q*, by two lines fastened to the hinder part of it, fixed upon hooks in the hopper, and by one end of the string *R* fastened to the fore part of it, the other end being twisted round the pin, *S*. By turning this pin one way, the string draws up the shoe closer to the hopper, and so lessens the aperture between them; and as the pin is turned the other way, it lets down the shoe, and enlarges the aperture. If the shoe be drawn up quite to the hopper, no corn can fall from the hopper into the mill; if it be let down a little, some will fall; and the quantity will be more or less, according as the shoe is more or less let down; for the hopper is open at the bottom, and there is a hole at the bottom of the shoe, not directly under the bottom of the hopper, but nearer to the lowest end of the shoe, over the middle or eye of the stone.

In a square hole at the top of the spindle, is put the feeder *E*, fig. 8. This feeder, as the spindle turns round, jogs the shoe three times in each revolution, and so causes the corn to run constantly down from the hopper through the shoe, into the eye of the mill-stone, where it falls upon the top of the rynd, and is, by the motion of the rynd, and the leather under it, thrown below the upper stone, and ground between it and the lower one. The rapid motion of the stone creates a centrifugal tendency in the corn going round with it, by which means it gets farther and farther from the centre, as in a spiral, in every revolution, until it is quite thrown out, and being then ground, it falls through a spout, called the mill-eye, into a trough placed for its reception.—When the mill is fed too fast, the corn bears up the stone, and it is ground too coarse; besides, the mill is apt to get clogged, and to go too slowly. When the corn is scantily supplied, the mill goes too fast, and the stones by their collision are apt to strike fire. Both these inconveniences are avoided, by turning the regulating pin, *S*, backward or forward, in order to draw up or let down the shoe, as the case is observed by the miller to require.

The heavier the running mill-stone, and the greater the quantity of water falling upon the wheel, the faster will the mill bear to be fed, and consequently the greater the performance of the mill. When the stone is considerably worn, and become light, its weight must either be increased by some artificial addition, or the mill must necessarily be fed slowly; otherwise the stone will be too much borne up by the corn under it, to grind the meal sufficiently fine. The power necessary to turn a heavy mill-stone, is but very little more than what is necessary to turn a light one; for as the stone is supported upon the spindle of the bridge-tree, and the end of the spindle that turns in the brass foot is but small, the difference arising from the weight produces only an inconsiderable action against the power or force of the water. Besides, a heavy stone affords the same

advantage as a heavy fly, that is, it regulates the motion much better than a light one, from its not being liable to such great fluctuations of velocity.

In order to cut and grind the corn, both the upper and under mill-stones have channels or furrows cut in them, proceeding obliquely from the centre to the circumference. These furrows, in the direction of their length, are cut slantwise on one side, and perpendicularly on the other, thus,  so that each of the ridges which they form has a sharp edge; and in the two stones, these edges pass one another like the edges of a pair of scissors, and so cut the corn, to make it grind the more easily, when it falls upon the furrows. The furrows are cut the same way in both stones, when they lie upon their backs, which makes them run crosswise to each other when the upper stone is inverted by turning its furrowed surface towards that of the lower, for, if the furrows of both stones lay the same way, part of the corn would be driven onward in the lower furrows, and come out from between the stones without being either ground or bruised. The grinding surface of the under stone is a little convex from the edge to the centre, and that of the upper stone a little concave; and they are farthest from one another in the middle, but approach gradually nearer towards the edges. By this means the corn, at its first entrance between the stones, is only bruised; but as it goes farther on towards the circumference or edge, it is cut smaller and smaller, and at last finely ground, just before it comes out from between them.

When the ridges become blunt and the furrows shallow by wearing, the running stone must be taken up, and both of them may then be dressed anew with a chisel and mallet. Every time the stone is taken up, there must be some tallow put round the spindle and upon the bush; this unguent will soon be melted by the heat the spindle acquires from its turning and rubbing against the bush, which it will prevent from taking fire.

The bush must embrace the spindle quite close, to prevent any shake in the motion, which would cause some parts of the stones to grate against each other, whilst the other parts of them would be too far asunder, and by that means spoil the meal. Hence, whenever the spindle has worn the bush, so as to begin to shake in it, the stone must be taken up, and a chisel driven into several parts of the bush; and when it is taken out, wooden wedges must be forced into the holes; by which means the bush will be made closely to embrace the spindle again all round. In doing this, great care must be taken to drive equal wedges into the bush on opposite sides of the spindle: otherwise it will be thrown out of the perpendicular, and so hinder the upper stone from being set parallel to the under one, which is absolutely necessary for making good work. When any accident of this kind occurs, the perpendicular position of the spindle must be restored, by adjusting the bridge-tree with proper wedges put between it and the brayer.

The rynd is sometimes wrenched in laying down the upper stone upon it, or is made to sink a little lower on one side of the spindle than on the other; and this will cause one edge of the upper stone to drag all round upon the lower, while the opposite edge will not touch. This is easily rectified, by raising the stone a little with a lever, and putting bits of paper, card, or thin chips, between the rynd and the stone.

Till the steam-engine came into general use, so as to make people independent of water and wind, and animal strength, as agents to drive machinery, the first-named was considered the best moving power; and wind the next, where water was denied; and they are still used as valuable and powerful movers in many situations. To illustrate the combinations of machinery, any of these might be taken. We shall, for this purpose, confine ourselves at present to

Water Mills. There are three descriptions of these, namely, Breast-mills, Undershot-mills, and Overshot-mills, according to the manner in which the water is applied to the great wheel. In the first, the water falls down upon the wheel at right angles to the float-boards or buckets placed all round the wheel to receive it. In the second, which is used where there is no fall but a considerable body of water, the stream strikes the float-boards at the lower part of the wheel. In the third, the water is poured over the top, and is received in buckets formed all round the wheel. According to Smeaton,

the power necessary to produce the same effect on the undershot-wheel, a breast-wheel, and an overshot wheel, must be to each other as the numbers 2·4, 1·75, and 1.

Rules for the Construction of Water-Mills:—1. Measure the perpendicular height of the fall of water, in feet, above that part of the wheel on which the water begins to act, and call that the height of the fall. 2. Multiply this constant number 64·2822 by the height of the fall in feet, and the square root of the product will be the velocity of the water at the bottom of the fall, or the number of feet that the water there moves per second. 3. Divide the velocity of the water by three, and the quotient will be the velocity of the float-boards of the wheel, or the number of feet they must each go through in a second, when the water acts upon them so as to have the greatest power to turn the mill. 4. Divide the circumference of the wheel in feet by the velocity of its floats in feet per second, and the quotient will be the number of seconds in which the wheel turns round. 5. By this last number of seconds divide 60, and the quotient will be the number of turns of the wheel in a minute. 6. Divide 120 (the number of revolutions a millstone four feet and a half in diameter ought to have in a minute) by the number of turns of the wheel in a minute, and the quotient will be the number of turns the millstone ought to have, for one turn of the wheel. 7. Then, as the number of turns of the wheel in a minute is to the number of turns of the millstone in a minute, so must the number of staves in the trundle be to the number of cogs in the wheel, in the nearest whole numbers that can be found.

The breadth of the water-wheel ought to correspond with the power necessary on the occasion, supposing that a proportionate volume of water is at command; for a wheel of two feet in breadth will be more than double as powerful as one only a foot broad, there being a double volume of water acting upon it, while the friction of the axis is by no means doubled with this augmentation of breadth.

It may be well to notice here Smeaton's discovery, that "the more slowly any body descends by the force of gravity while acting upon any piece of machinery, the more of that force will be spent upon it, and consequently the effect will be the greater." That effect is not increased in proportion to the velocity of the wheel's motion. Smeaton found, that when the wheel with which he experimented (two feet in diameter) revolved 20 times in a minute, its effect was greatest; when it made only 18½ turns, the effect was irregular; and when so laden as not to make 18 turns, the wheel was overpowered by the load: thirty turns in the minute occasioned a loss of about one-twentieth; and when turned above 30 times in a minute, the diminution of effect was nearly one-fourth of its powers. This proportion may be easily estimated on any wheel of greater extent, by computing the proportion of accumulated power lost by greater velocity than may be sufficient to load the wheel by means of the buckets being filled; observing, that the progress of a machine may be so much retarded as to cause the effect to be irrelevant to the purpose, although the machine may be kept in motion.

To compute the effects of water-wheels, ascertain, 1. The real velocity of the water which acts upon the wheel; 2. the quantity of water expended in a given time; and 3. how much of the power is lost by friction. Smeaton found that the mean power of a volume of water 15 inches in height, gave 8·96 feet of velocity in each minute to a wheel on which it impinged. The computation of the power to produce such an effect, allowing the head of water to be 105·8 inches, gave 264·7 pounds of water descending in one minute through the space of 15 inches, therefore 264·7, multiplied by 15, was equal to 3970. But as that power will raise no more than 9·375 pounds to the height of 135 inches, it was manifest that the major part of the power was lost; for the multiplication of these two sums only amounted to 1·266; of course the friction was equal to three-fourths of the power. According to Smeaton, this is the maximum single effect of water upon an undershot-wheel, where the fall is fifteen inches. The remainder of power, it is plain, must equal that of the velocity of the wheel itself, multiplied into the weight of the water, which in this case brings the true proportion between the power and the effect to be as 3·849 to 1·266, or as 11 to 4.

In Undershot mills, the float-boards should be rather numerous than few. Smeaton found when he reduced them from 24 to 12, that the effect was reduced one-half, because the water escaped between the floats without touching them; but when he added a circular sweep of such length, that before one float board quitted it, another had entered it, he found the former effect nearly restored. This mode more particularly applies to breast wheels, or such as receive the water immediately below the level of the axis. In such, the float boards should be confined both at their sides and at their extremities, so that the water may accompany them all the way from the head down to the lowest part of the wheel, whence it should pass off with sufficient readiness to allow the succeeding fall to supply its place, without being in the least retarded. It has been ascertained, that a very sensible advantage is gained by inclining the float-boards to the radius of the wheel, so that each float-board, when lowest, shall have its edge turned up the stream about twenty degrees.

The Overshot wheel is the most powerful, giving a result equal to four-fifths of the power.

The Breast wheel, well constructed, yields a half or 3-5ths of the power. But often, from inattention to the reduction of friction, and inaccurate workmanship, the power not only of this, but of the preceding forms also, is greatly reduced.

The teeth of wheels ought not to act upon each other before they arrive at the line which joins their centres; and though the inner or under side of the teeth may be of any form, yet it is better to make both sides alike, that the wheels may admit of being revolved either way with equal facility. The teeth should be made as fine as the case admits, so that the greatest number possible may be in contact at once; and the utmost care should be taken to have them so regularly disposed that they may not interfere with each other before they begin to work; and they should be so formed that the pressure by which one of them urges the other round its axis, may be constantly the same. This is by no means the case, when the common construction of a spur wheel, acting in the cylindrical staves of a lantern or trundle, is used. The ends of teeth should never be formed of parts of circles, unless working with other teeth, specifically adapted to them.

Method of Setting out Wheels.—For a Spur-wheel and Trundle, Lantern or Wallower, draw the pitch lines A 1, B 1, A 2, B 2, fig. 1, plate III., then divide the number of teeth or cogs required, as *a b c*. Divide one of these distances, as *b c*, into 7 equal parts, as 1, 2, 3, 4, 5, 6, 7: allow 3 for the thickness of the cogs, as 1, 2, 3, in the cog *a*; and 4 for the diameter of the stave of the trundle, as 1, 2, 3, 4, in the stave *m*, fig. 2. Three parts are allowed for the cog, and 4 for the stave, the wallower being supposed to be of less diameter than the wheel, therefore subject to more wear, in proportion as the number of cogs exceed the number of staves; but if in any case the number of staves and cogs be the same, they may be of equal thickness. The height of the cog is equal to 4 parts; then divide its height into 5 equal parts, as 1, 2, 3, 4, 5 in the cog *c*; allow 3 for the bottom to the pitch line of the cog; the other 2 for the curve which must be given it, to make it fit and bear on the stave equally.

In common practice, the millwrights are accustomed to put the point of a pair of compasses in the dot 3 of the cog *a*, and strike the line *d f*; then they remove the point of the compasses to the point *d*, and strike the curve *3 e*, by which means they obtain a curve which they consider sufficiently correct.

For a face-wheel, divide the pitch-line A B, fig. 2, into the number of cogs intended, as *a b c*; divide the distance *b c* into 7 equal parts; allow 3 of these for the thickness of the cogs, as 1, 2, 3, in the cog *a*, 4 for the height, and 4 for the width, as *d e*, and 4 for the thickness of the stave *m*. Draw a line through the centre of the cog, as the line A 1, at S; and on the point 5 describe the line *d e*; remove the compasses to the point A, and draw the line *f g*, by which the shape of the cog will be determined.

For common spur nuts, divide the pitch-line, A, fig. 3, into twice as many equal parts as there are intended to be teeth, as *a, b, c, d, e*; with a pair of compasses open to half the distance of any of these divisions, from the points *a 1, c 3, e 5*, draw the semicircles *a, c*, and *e*, which will form the ends of the

teeth. From the points 2, 4, and 6, draw the semicircles g, h, i , which will form the lower parts of the spaces. Though spur-nuts are usually set out in this manner, yet in good work, the ends of the teeth must not be semicircles, unless working with other teeth adapted to them, but epicycloids.

Of Bevel Gear.—Bevelled wheels, commonly called bevel-geer, which have nearly superseded the spur wheels and trundles, are, in effect, truncated cones, rolling on the surface of each other. Suppose the cones A and B, revolving on their centres a, b , fig. 4, plate III.; if their bases are equal, they will perform their revolutions in equal times, and consequently any two points equally distant from the centre a of A, as a, b, c, d, e , will revolve in the same time as a, f, g, h, i . If one of the cones, as in fig. 5, be twice the diameter of the other, the base of the larger will make one revolution, while that of the smaller will make two; and all the corresponding parts of the conical surfaces will observe the same proportion; that is, a, b, c, d, e , will turn only once round, while a, f, g, h, i , turn twice round; the number of the revolutions of all cones revolving in this manner, being to each other as their respective diameters. Let two cones have teeth cut in them, as represented by fig. 6; they will become bevel-geer. These teeth would be broadest at the base, from whence they would gradually taper with the lessening circumference of the cone, till they terminated at the apex a in a point; but as such an extent of teeth would be unnecessary, the useless parts of the teeth are cut off, as at B and F; that is, bevel-geer is composed of wheels made in the form of truncated cones, as shown by fig. 7, where the upright shaft AB, with the bevel-wheel CD, turns the bevel-wheel EF, with its shaft GH, and the teeth work freely in each other.

The method of conveying motion in any direction, and of proportioning or shaping the wheels accordingly, is as follows: let the line ab , fig. 8, plate III. represent the shaft coming from a wheel; draw the line cd to intersect the line ab in the direction intended for the motion to be conveyed, and this line cd will represent the shaft of the bevel-wheel which is to receive the motion. Suppose then the shaft c is to revolve three times, whilst the shaft a b revolves once; draw the parallel line ii at any moderate distance, (suppose one foot by a scale,) then draw the parallel line kk , at three feet distance, after which draw the dotted line wx , through the intersection of the shaft a b and c d , and likewise through the intersection of the parallel lines ii and kk , in the points x and y , which will be the pitch-line of the two bevel-wheels, or the line where the teeth of the two wheels act on each other, as may be seen by fig. 9, where it is obvious to inspection that the motion may be conveyed in any direction.

In crown wheels and bevelled geer, the faces of the teeth must be all tapered, as if they proceeded from a common centre. The pinion may be considered as a portion of a cone, which, rolling along the horizontal rim of the wheel, traces the contour of the teeth, by describing a modified epicycloid. The same general principles indicate all the variations. It is of practical consequence that the teeth of wheels should all be equally worn. In their mutual congress, therefore, they ought to produce a series of the most diversified contacts. To effect this object, the number of teeth in the pinion and the wheel must be as discordant as possible. If the one were any aliquot part of the other, the same incessant coincidence would soon recur, occasioning a partial and disproportionate attrition. Prime numbers should be preferred, and the larger they are, the smoother will the wheels work. The odd tooth in the pinion is by our mill-wrights very appositely called the *hunting cog*.

The effects produced by machines are extremely diversified. To extend action to a distance, or to divert its direction, to reduce or multiply the celerity impressed; to modify an uniform progression into an accelerating or retarding one; to maintain a parallel motion; to change a rectilinear into a circular motion, and the reverse; to convert a reciprocating play into a constant circulation or equable rectilinear flow;—these are a few of the objects generally aimed at. Pressure is conveyed to any distance, by a system of parallel levers, supported at certain intervals, the extremities of their arms being connected by a train of beams. The direction of any power is

easily changed, by means of a crank or bent lever. The same contrivance, aided by the action of a fly, converts a reciprocating into a circular motion. This effect is likewise produced by a rack, working alternately on the opposite sides of a toothed wheel. The celerity is modified at pleasure, by affixing to the axle solid blocks, sometimes called *heart wheels*, and fashioned like spiral or eccentric curves. These lines may be traced with such accuracy as to evolve the precise succession of impulse required. But all the transitions should, if possible, be gradual, any sudden change occasioning a concussion which wastes the force, and tends to disjoint and shatter the parts of the machine.

The most elegant mode of transmitting force in any direction, is by a contrivance termed the *Universal Joint*, (see the Plate, fig. 10.) Instead of the cross, a ring or a ball is often preferred. But the angular motion communicated in this way is not quite equable, and becomes even irregular in the case of great obliquity. By doubling, however, the combination of axes, the impression may be turned aside almost into an opposite direction, and may be rendered uniform by a compensation of irregularities.

An alternate motion is beautifully converted into a revolving one, by a vertical rod which carries affixed to it a wheel indented to another wheel of the same size. The central wheel, describing at each reciprocation a double circumference, must turn twice round. This mechanism is, from a vague analogy, called the *Sun and Planet Wheel*. A reciprocating beam can be made to raise and depress a rod very nearly in a vertical line, by means of a regulated parallelogram. Thus, as in the figure, C being the centre of the beam, let an arm BE turn about the

firm joint B, and guide the end E of the parallelogram ADEF; if CD be taken a mean proportional to AD and BE, the other end F, carrying the rod of a piston, will travel in a path which is very nearly rectilinear and perpendicular. These two fine contrivances were happily combined in Watt's Steam Engine.

MECHANICAL Surgery, is a branch of the profession, the object of which is, by mechanical means, to relieve or to remedy certain deformities or injuries to which some persons are subject from their birth, but which in many cases are the result of accident.

MEDAL denotes a piece of metal in the form of coin, such as was either current money among the ancients, or struck on any particular occasion, to preserve the portrait of some great person, or the memory of some illustrious action, to posterity. As historical documents, they form the principal evidence we can have of the truth of the old historians. In some few instances they correct the names of sovereigns; and in a great many, illustrate the chronology of reigns. By their assistance the geographer has sometimes been enabled to determine the situation of a town whose name alone has reached us. To the naturalist they afford the only proofs of the knowledge which the ancients had of certain plants and animals; and they sometimes preserve delineations of buildings for the architect, of which not even a ruin is at this day standing.

MEDALLION, or **MEDALION**, a medal of an extraordinary size, supposed to be anciently struck by the emperors for their friends, and for foreign princes and ambassadors. But, that the smallness of their number might not endanger the loss of the devices they bore, the Romans generally took care to stamp the subject of them upon their ordinary coin. Medallions, in respect of the other coins, were the same as modern medals in respect of modern money: they were exempted from all commerce, and had no other value than what was set upon them by the fancy of the owner. Medallions are so scarce, that there cannot be any set made of them, even though the metals and sizes should be mixed promiscuously.

MEDEOLA, *Climbing African Asparagus*, a genus of plants

belonging to the hexandria class, and in the natural method ranking under the 11th order, samentaceæ.

MEDIANA, the name of a vein or little vessel, made by the union of the cephalic and basilic in the bend of the elbow.

MEDIASTINUM, in Anatomy, a double membrane, formed by a duplicature of the pleura; serving to divide the thorax and the lungs into two parts, and to sustain the viscera, and prevent their falling from one side of the thorax to the other. See **ANATOMY**.

MEDIATE, or **INTERMEDIATE**, something that stands betwixt and connects two or more terms considered as extremes; in which sense it stands opposed to *immediate*.

MEDIATOR, a person that manages or transacts between two parties at variance, in order to reconcile them. The word, in scripture, is applied, 1. To Jesus Christ, who is the only intercessor and peace-maker between God and man, (1 Tim. ii. 5.) 2. To Moses, who interposed between the Lord and his people, to declare unto them his word, (Deut. v. 5. iii. 19.)

MEDICAGO FALCATA. *Yellow Medic.*—Is nearly allied to lucerne, and is equally good for fodder; it will grow on land that is very dry, and hence is likely to become a most useful plant; its culture has, however, been tried but partially. Some experiments were made with this plant by Thomas Le Blanc, Esq., in Suffolk, which are recorded by Professor Martyn.

MEDICAGO POLYMORPHA. *Variable Medic.*—This is also a plant much relished by cattle, but is not in cultivation: it is an annual, and perhaps inferior in many respects to the *Nonsuch*, which it in some measure resembles. There are many varieties of this plant cultivated in flower gardens on account of the curious shapes of the seed-pods, some having a distant resemblance to snails' horns, caterpillars, &c. under which names they are sold in the seed-shops. It grows in sandy hilly soils; the wild kind has flat pods.

MEDICAGO SATIVA. *Lucerne*.—Too much cannot be said in praise of this most useful perennial plant: it is every thing the farmer can wish for, excepting that it will not grow without proper culture. It should be drilled at eighteen inches distance, and kept constantly hoed all summer, have a large coat of manure in winter, and be dug into the ground between the drills. Six or seven pounds of seed will sow an acre in this mode. *Lucerne* is sometimes sown with grass and clover for forming meadow land; but as it does not thrive well when encumbered with other plants, no good can be derived from the practice. No plant requires, or in fact deserves, better cultivation than this, and few plants yield less if badly managed.

MEDICAGO LUPULINA. *Trefoil*, or *Nonsuch*.—A biennial plant, very usefully cultivated with rye-grass and clover for forming artificial meadows. Trefoil when left on the ground will seed, and these will readily grow and renew the plant successively; which has caused some persons to suppose it to be perennial. About eight or ten pounds of seed are usually sown with six or eight pecks of rye-grass for an acre, under a crop of barley or oats.

MEDICAGO, *Snail Trefoil*, a genus of plants belonging to the diadelphia class, and in the natural method ranking under the 32d order, papilionaceæ. See *Green's Botanical Dictionary*. For the properties and culture of *Lucerne*, a species of this genus, see **AGRICULTURE**.

MEDICINAL, any thing belonging to medicine.

MEDICINAL Springs, a general name for any fountain, the waters of which are of use for removing certain disorders. They are commonly either chalybeate or sulphurous. See **SPRINGS** and **WATER**.

MEDICINE, the art of preventing, curing, or alleviating those diseases to which the human body is subject, is of very great antiquity, for we find that the sacred historian styles those servants to Joseph, who embalmed the body of the patriarch Jacob, "physicians." Joseph was then in Egypt, the cradle of science, where *Hioth*, the inventor of the art, shared divine honours with Osiris and Isis. Esculapius was the most eminent practitioner among the Greeks, and the writings of Hippocrates are the most ancient on this art, since they were penned 400 years before Christ. This sage judged of diseases from the look, posture of the patient in bed, from respiration, the excrementitious discharges, expectoration, sweat, and the

pulse. His maxims for the preservation of health are, temperance, exercise, and labour. His maxims for the cure of diseases are, that evacuations cure those diseases which come from repletion, and repletion those caused by evacuations. The first physician of eminence who differed considerably in his practice from Hippocrates was Praxagoras. Coelius Aurelianus acquaints us, that he made great use of vomits in his practice, insomuch as to exhibit them in the iliac passion till the excrements were discharged by the mouth. In this distemper he also advised, when all other methods failed, to open the belly, cut the intestine, take out the indurated fæces, and then to sew up all again; but this practice has not probably been followed by any subsequent physician. This man had for a disciple the famous Herophilus, who was contemporary with Erasistratus, a physician of great eminence, who flourished in the time of Seleucus, one of the successors of Alexander the Great.

Celsus, who lived in the time of Tiberius, ranks next to Hippocrates as a medical writer and physician. Galen, a native of Pergamus, made a great figure as a writer and practitioner in this art during the reign of Adrian. Time would fail us to name all the useful and empiric physicians who flourished from that period till the downfall of the Roman empire, when the inundation of Goths and Vandals had almost completely exterminated literature of every kind in Europe, and medicine, though a practical art, shared the same fate with more abstract sciences. Learning in general, banished from the seat of arms, took refuge among the eastern nations, where the arts of peace still continued to be cultivated. To the Arabian physicians, as they have been called, we are indebted both for the preservation of medical science, as it subsisted among the Greeks and Romans, and likewise for the description of some new diseases, particularly the small pox. Among the most eminent of the Arabians, we may mention Rhases, Avicenna, Albucasis, and Avenzoar. But of their writings it would be tedious, and is unnecessary, to give any particular account. They were for the most part, indeed, only copiers of the Greeks. We are, however, indebted to them for some improvements. They were the first who introduced chemical remedies, though of these they used but few, nor did they make any considerable progress in the chemical art. Anatomy was not in the least improved by them, nor did surgery receive any advancement till the time of Albucasis, who lived probably in the 12th century. They added a great deal to botany and the materia medica, by the introduction of new drugs, of the aromatic kind especially, from the East, many of which are of considerable use. They also found out the way of making sugar; and by help of that, syrups; which two new materials are of great use in mixing up compound medicines.

In the beginning of the 16th century, the famous chemist Paracelsus introduced a new system into medicine, founded on the principles of chemistry. The Galenical system had prevailed till his time; but the practice had greatly degenerated, and was become quite trifling and frivolous. The physicians in general rejected the use of opium, mercury, and other efficacious remedies. Paracelsus, who made use of them, had therefore greatly the advantage over them; and now all things relating to medicine were explained on imaginary chemical principles. It will easily be conceived, that a practice founded in this manner could be no other than the most dangerous quackery. The discovery of the circulation of the blood in the year 1528, opened a new era in medicine, which the abilities of Stahl, Hoffman, Boerhaave, Cullen, and Dr. James Gregory, have further extended.

Medicine, in examining the functions of the human body, considers those that relate to itself only, and others to external things. To the latter class belong those which, by physicians, are called the *animal functions*; to which are to be referred all our senses, as well as the power of voluntary motion, by which we become acquainted with the universe, and enjoy this earth. Among the functions which relate to the body, some have been named *vital*, such as the circulation of the blood and respiration; because, without the constant continuance of these, life cannot subsist; others, intended for repairing the waste of the system, have been termed the *natural functions*; for by the

constant attrition of the solids and the evaporation of the fluid parts of the body, we stand in need of nourishment to supply the waste; after which the putrid and excrementitious parts must be thrown out by the proper passages. The digestion of the food, secretion of the humours, and excretion of the putrid parts of the food, are referred to this class; which, though necessary to life, may yet be interrupted for a considerable time without danger. This division of the functions into animal, vital, and natural, is of very ancient date, and is perhaps one of the best that has yet been proposed.

Distinction of Diseases into Simple and Compound. A disease takes place when the body has so far declined from a sound state, that its functions are either quite impeded, or performed with difficulty. A disease therefore may happen to any part of the body either solid or fluid, or to any one of the functions; and those may occur either singly, or several of them may be diseased at the same time; whence the distinction of diseases into simple and compound. We have examples of the most simple kinds of diseases, in the rupture or other injury of any of the corporeal organs, by which means they become less fit for performing their offices; or, though the organs themselves should remain sound, if the solids or fluids have degenerated from a healthy state; or if, having lost their proper qualities, they have acquired others of a different, perhaps of a noxious nature; or, lastly, if the moving powers shall become too weak or too strong, or direct their force in a way contrary to what nature requires.

Symptoms. The most simple diseases are either productive of others, or of symptoms, by which alone they become known to us. Every thing in which a sick person is observed to differ from one in health is called a symptom; and the most remarkable of these symptoms, which most commonly appear, define and constitute the disease.

Predisponent Cause. The causes of diseases are various; often obscure, and sometimes totally unknown. The most full and perfect proximate cause is that which, when present, produces a disease; when taken away, removes it; and when changed, changes it.—There are also remote causes, which physicians have been accustomed to divide into the predisponent and exciting ones. The former are those which only render the body fit for a disease, or which put it into such a state that it will readily receive one. The exciting cause is that which immediately produces the disease in a body already disposed to receive it.

Exciting Cause. The predisponent cause is always inherent in the body itself, though perhaps it originally came from without; thus heat or cold, a very sparing or a very luxurious diet, and many other particulars, may operate as causes of predisposition, inducing plethora, inanition, or the like: but the exciting cause may either come from within or without.

Proximate Cause. From the combined action of the predisponent and exciting causes comes the proximate cause, which neither of the two taken singly is often able to produce. A body predisposed to disease therefore has already declined somewhat from a state of perfect health, although none of its functions are impeded in such a manner that we can truly say the person is diseased. Yet sometimes the predisponent cause, by continuing long, may arrive at such a height, that it alone, without the addition of any exciting cause, may produce a real disease. The exciting cause also, though it should not be able immediately to bring on a disease; yet if it continues long, will by degrees destroy the strongest constitution, and render it liable to various diseases; because it either produces a predisponent cause, or is converted into it, so that the same thing may sometimes be an exciting cause, sometimes a predisponent one, or rather a cause of predisposition; of which the inclemencies of the weather, sloth, luxury, &c. are examples.

Hereditary Diseases. Diseases, however, seem to have their origin from the very constitution of the animal machine; and hence many diseases are common to every body when a proper exciting cause occurs, though some people are much more liable to certain diseases than others. Some are hereditary; for as healthy parents naturally produce healthy children, so diseased parents as naturally produce a diseased offspring. Some of these diseases appear in the earliest infancy; others occur equally at all ages; nor are there wanting some which

lurk unsuspected even to the latest old age, at last breaking out with the utmost violence. Some diseases are born with us, even though they have no proper foundation in our constitution, as when a foetus receives some hurt by an injury done to the mother; while others, neither born with us, nor having any foundation in the constitution, are suckled in with the nurse's milk.

Diseases from Age and Sex. Many diseases accompany the different stages of life; and hence some are proper to infancy, youth, and old age. Some also are proper to each of the sexes; especially the female sex, proceeding, no doubt, from the general constitution of the body, but particularly from the state of the parts subservient to generation. Hence the diseases peculiar to virgins, to menstruating women, to women with child, to lying-in women, to nurses, and to old women.

Diseases from Climate. The climate itself, under which people live, produces some diseases; and every climate has a tendency to produce particular diseases, either from its excess of heat or cold, or from the mutability of the weather. An immense number of diseases also may be produced by impure air, or such as is loaded with putrid, marshy, and other noxious vapours. The same thing may happen likewise from corrupted aliment, whether meat or drink; though even the best and most nutritious aliment will hurt if taken in too great quantity; not to mention poisons, which are endowed with such pernicious qualities, that even when taken in a very small quantity they produce the most grievous diseases, or perhaps even death itself. Lastly, from innumerable accidents and dangers to which mankind are exposed, they frequently come off with broken limbs, wounds, and contusions, sometimes quite incurable; and these misfortunes, though proceeding from an external cause, often terminate in internal diseases.

Diseases from Passions of the Mind. Besides the dangers arising from those actions of the body and mind which are in our own power, there are others arising from those which are quite involuntary. Thus, passions of the mind, either when carried to too great excess, or when long continued, equally destroy the health; nay, will even sometimes bring on sudden death. Sleep also, which is of the greatest service in restoring the exhausted strength of the body, proves noxious either from its too great or too little quantity. In the most healthy body also, many things always require to be evacuated. The retention of these is hurtful, as well as too profuse an evacuation, or the excretion of those things either spontaneously or artificially, which nature directs to be retained. As the solid parts sometimes become flabby, soft, almost dissolved, and unfit for their proper offices; so the fluids are sometimes inspissated, and formed even into the hardest solid masses. Hence impeded action of the organs, vehement pain, various and grievous diseases. Lastly, some animals are to be reckoned among the causes of diseases; such, particularly, as support their life at the expense of others; and these either invade us from without, or take up their residence within the body, gnawing the bowels while the person is yet alive, with great danger and distress.

It would be foreign to our purpose to enter upon any analysis of the animal solids, their qualities, &c.; nor can we do more than enumerate the vital solids, or those which enjoy sense and mobility, as feeling, pain, anxiety, itching, taste, smell, hearing, sight, vertigo; memory, delirium, melancholy, and idiotism, which four last are properly internal senses. The disorders in the muscular power arise from too great mobility, vigour, torpor, debility, palsy, spasm;—sleep, the circulation of the blood, the pulsation of the arteries, palpitation, syncope, are all different disorders from the former; and diseases of the blood arise from plethora, inanition, morbid thinness, thickness, and acrimony;—the disorders of respiration are, coughs and sneezings; those of digestion embrace costiveness and looseness; such as proceed from the disorganization of the alimentary canal, are, dysentery, tetanus, nausea, iliac passion, vomiting, cholera; from disorders in the secretory organs proceed excessive perspiration, suppression of urine, dysuria, strangury, urinary calculi, and scirrhus.

MEDIETAS LINGUÆ, a jury or inquest, whereof the one-half consists of denizens, the other strangers, in pleas, wherein the one party is a stranger.

MEDIUM, in Logic, the mean or middle term of a syllogism, being an argument, reason, or consideration for which we affirm or deny any thing: or, it is the cause why the greater extreme is affirmed or denied of the less, in the conclusion.

MEDIUM, in Arithmetic, or *Arithmetical Medium* or *Mean*, that which is equally distant from each extreme, or which exceeds the lesser extreme as much as it is exceeded by the greater, in respect of quantity, not of proportion; thus, 9 is a medium between 6 and 12.

MEDIUM, *Geometrical*, is that where the same ratio is preserved between the first and second, as between the second and third terms, or that which exceeds the same ratio, or quota of itself, as it is exceeded: thus, 6 is a geometrical medium between 4 and 9.

MEDIUM, in Philosophy, that space or region through which a body in motion passes to any point: thus, æther is supposed to be the medium through which the heavenly bodies move.

MEDIUM, *Subtile* or *Æthereal*. Sir Isaac Newton makes it probable, that besides the particular aerial medium, wherein we live and breathe, there is another more universal one, which he calls an æthereal medium, vastly more rare, subtile, elastic, and active than air, and by that means freely permeating the pores and interstices of all other mediums, and diffusing itself through the whole creation; and by the intervention hercof, he thinks it is, that most of the great phenomena of nature are effected.

MEDUSA, in Natural History, a genus of the vermes mollusca class and order. They consist of a tender gelatinous mass of different figure, with arms proceeding from the lower surface: the larger species, when touched, cause a slight tingling and redness, and are usually denominated sea-nettles; they are supposed to constitute the chief food of cetaceous fish. Most of them shine with great splendour in the water.

MELANCHOLY, a species of insanity, supposed to arise from a redundancy of bile, which from disease becomes of a dark colour. See **MEDICINE**.

MELASIC ACID, found in molasses, supposed to be the same as the acetic acid.

MELEAGRIS, in Natural History, the turkey, a genus of birds of the order gallinae. The wild turkey is a native of America, the presumed origin of every species under the genus. In the northern parts of that continent these birds are found in flocks of several hundreds, which during the day-time resort to the woods, feeding principally upon acorns, returning by night to some swampy grounds, where they roost upon the highest trees. In Carolina they occasionally grow to the weight of thirty pounds. Turkeys breed only once in a year, but will produce a great number at a time, sometimes seventeen. The female sits with extreme closeness, and is very assiduous in maternal duties. The young, however, are very susceptible of injury, from almost innumerable causes, from cold and wet, and even sunshine itself.

MELISSA OFFICINALIS. *Balm*.—This herb, in its recent state, has a weak, roughish, aromatic taste, and a pleasant smell, somewhat of the lemon kind. On distilling the fresh herb with water, it impregnates the first runnings pretty strongly with its grateful flavour. Prepared as tea, however, it makes a grateful diluent drink in fevers; and in this way it is commonly used, either by itself, or acidulated with the juice of lemons.

MELITTIS MELISSOPHYLLUM, and **MELITTIS GRANDIFLORA**. *Bastard Balm*.—Both these plants are very beautiful, and are deserving a place in the flower garden: they are of easy culture, and will grow well under the shade of trees, a property that will always recommend them to the notice of the curious.

MELLATES, in Chemistry, a genus of salts formed from the mellitic acid.

MELLITE, or **HONEY STONE**, in Mineralogy, takes its name from its yellow colour like that of honey. Its primitive figure is an octahedron. The crystals are small, their surface is commonly smooth and shining. Internally it is splendid. It is transparent, passing into the opaque, and possesses a double refraction. It is softer than amber, and brittle. Specific gravity is from about 1.6 to 1.7. It becomes electric by friction, but continues so only a short time. This mineral occurs on

bituminous wood, an earthy coal, and is commonly accompanied with sulphur.

MELLITIC ACID, is procured from mellite reduced to powder, and boiled with about seventy-two times its weight of water, the alumina is precipitated in the form of flakes, and the acid combines with the water. By filtration and evaporation, crystals are deposited in the form of fine needles, or in small short prisms. The acid is not very soluble in water; its constituent parts are carbon, hydrogen, and oxygen. In combination with the earths, alkalies, and metallic oxides, it forms compounds denominated mellates.

MELODRAME. See **DRAMA**. A modern word for dramatic performances in which songs are intermixed.

MELODY, in Music, the agreeable effect of different sounds, ranged and disposed in succession, so that melody is the effect of a single voice or instrument, by which it is distinguished from harmony.

MELOE, a genus of insects of the order coleoptera. Thirty-five species have been described. The oil beetle, entirely blue-black or dark violet, is found in the advanced state of spring, in fields and pastures, creeping slowly, the body appearing so distended with eggs as to cause the insect to move with difficulty. On being roughly touched, it suddenly exudes a moisture from the pores, of a yellow colour, and of a very penetrating and peculiar smell. The female of this species deposits her eggs in a heap beneath the surface of the ground; from these are hatched the larvæ, which find subsistence by attaching themselves to other insects, and absorbing their juices. The blister-fly, or Spanish-fly, found chiefly in Spain, is an insect of great beauty, being entirely of the richest gilded grass green, with black antennæ. This is the cantharis of the shops, and the safest and most efficacious application for a blister plaster.

MENDICANTS, several orders of friars, who having no settled revenue, are supported by charitable contributions.

MENISCUS, a little moon, or rather a half-moon. A glass, concave on one side and convex on the other; as a watch glass.

MENISPERMIC ACID, supposed to be found in the menispermum cocculus.

MENNONITES, a sect who believe that the New Testament is the only rule of faith; that the terms *person* and *trinity* are not to be used when speaking of the Father, Son, and Holy Ghost; that the first man was not created perfect; that it is unlawful to swear or to wage war upon any occasion; that infants are not the proper subjects of baptism; and that ministers of the gospel ought to receive no salary.

MENSTRUUM, *Solvent* or *Dissolvent*, any fluid that possesses the property of dissolving or separating the parts of solid bodies.

MENSURABILITY, capacity of being measured.

MENSURATION, that branch of Mathematics which treats of the measurement of the extensions, capacities, solidities, &c. of bodies; and which, in consequence of its very extensive applications to the various purposes of life, may be justly considered as one of the most important of mathematical sciences. It is highly probable, that this science in its more simple state may be traced to the origin of human society. When men began to multiply, and turn their attention to the cultivation of the earth, it became necessary to have some means of distinguishing the portions belonging to each individual or family, both as to situation and quantity. The same necessity dictated some means for enumerating their flocks and herds. Hence, the former gave rise to mensuration, and the latter to arithmetic. But although the invention of mensuration cannot be attributed to any one person or nation, its existence may be traced to Egypt at a very early age, where, though in its infancy, it assumed a scientific form, immediately connected with the overflowing of the Nile. After the Egyptians, the Greeks embodied this science into something like a regular system, and to them we are indebted for its elementary principles. In some of its kindred departments, Euclid, Archimedes, and Cavalieri have gained immortality; and until this science shall be lost, the names of Bonycastle and Hutton cannot be forgotten. It is not consistent with the plan of this work to enter into details, but the clearness, simplicity, and rationality

of its simple principles, may be gathered from the following observations:—Every quantity is measured by some other quantity of the same kind; as a line by a line, a surface by a surface, and a solid by a solid; and the number which shews how often the lesser, called the measuring unit, is contained in the greater, or quantity measured, is called the content of the quantity so measured. Thus, if the quantity to be measured be the rectangle *A B C D*, and the little square *E*, whose side is one inch, be the measuring unit, then, as often as the said little square is contained in the rectangle, so many square inches the rectangle is said to contain: so that if the length *D C* be supposed 5 inches, and the breadth *A D* 3 inches, the content of the rectangle will be 3 times 5, or 15 square inches: because, if lines be drawn parallel to the sides, at an inch distance one from another, they will divide the whole rectangle *A B C D* into 3 times 5, or 15 equal parts, of one inch each. And, generally, whatever the measures of the two sides may be, it is evident that the rectangle will contain the square *E*, as many times as the base *A B* contains the base of the square, repeated as often as the altitude *A D* contains the altitude of the square. Hence we have the following rule for any parallelogram whatever:—To find the area of a parallelogram, whether it be a square, a rectangle, a rhombus, or a rhomboides. Multiply the length by the perpendicular height, and the product will be the area.

MENTHA VIRIDIS. *Spear-mint.*—The virtues of mint are those of a warm stomachic and carminative: in loss of appetite, nausea, continual retchings to vomit, and (as Boerhaave expresses it) almost paralytic weaknesses of the stomach, there are few simples perhaps of equal efficacy. In colicky pains, the gripes to which children are subject, henteries, and other kinds of immoderate fluxes, this plant frequently does good service. It likewise proves beneficial in sundry hysterical cases, and affords an useful cordial in languors and other weaknesses consequent upon delivery. The best preparations for these purposes are, a strong infusion made from the dry leaves in water (which is much superior to one from the green herb) or rather a tincture or extract prepared with rectified spirit. The essential oil, a simple and spirituous water, and a conserve, are kept in the shops: the Edinburgh College directs an infusion of the leaves in the distilled water. This herb is an ingredient also in the three alexiterial waters; and its essential oil, in the stomach plaster and stomachic pills.

MENTHA PIPERITA. *Pepper-mint.*—The leaves have a more penetrating smell than any of the other mints, and a much warmer, pungent, glowing taste like pepper, sinking as it were into the tongue. The principal use of this herb is in flatulent colics, languors, and other like disorders; it seems to act as soon as taken, and extends its effects through the whole system, instantly communicating a glowing warmth. Water extracts the whole of the pungency of this herb by infusion, and elevates it in distillation. Its official preparations are an essential oil, and a simple and spirituous water.

MENTHA PULEGIUM. *Pennyroyal.*—Pennyroyal is a warm purgative herb of the aromatic kind, similar to mint, but more acrid and less agreeable. It has long been held in great esteem, and not undeservedly, as an aperient and deobstruent, particularly in hysterical complaints, and suppressions of the uterine purgations. For these purposes, the distilled water is generally made use of, or, what is of equal efficacy, an infusion of the leaves. It is observable, that both water and rectified spirit extract the virtues of this herb by infusion, and likewise elevate greatest part of them in distillation.

MENYANTHES TRIPOLIATA. *Buck-bean.*—The leaves of this plant yield an efficacious aperient and deobstruent; it promotes the fluid secretions, and, if liberally taken, gently loosens the belly. It has of late gained great reputation in scorbutic and scrofulous disorders; and its good effects in these cases have been warranted by experience: inveterate cutaneous diseases have been removed by an infusion of the leaves, drunk to the quantity of a pint a day, at proper intervals, and continued some weeks. Boerhaave relates, that he was relieved of the goat by drinking the juice mixed with whey.

MENYANTHES NYMPHOIDES. *Round-leaved Dog Bean.*—This is a beautiful aquatic, and claims a place in all ornamental pieces of water.

MERCATOR, GERARD, an eminent geographer and mathematician, was born in the Low Countries in 1612; to whom we are indebted for the construction of those sea-charts called after him Mercator's charts, as also for that part of navigation which is after him called Mercator sailing. He died at Dolebourg in 1694.

Mercator, *Nicholas*, a celebrated mathematician and astronomer, was born at Holstein in 1640; but spent all the latter part of his life in England, and was admitted a fellow of the Royal Society. He is said to have possessed considerable talents, but was not of a very liberal turn of mind. Having made himself master of the analogy between a scale of logarithmic tangents and Wright's protractor of the nautical meridial line, which consisted of the sums of the secants, though it did not appear by whom this analogy was first discovered, and being desirous of making the most advantage of this and another invention in navigation, he, by a paper in the *Phil. Trans.* for June, 1693, invited the public to enter into a wager with him on his ability to prove the truth or falsehood of the supposed analogy! This proposal, not very reputable to a man of science and literature, was not taken up by any one, and Mercator reserved his demonstration; he however distinguished himself by many valuable pieces on philosophy and mathematical subjects. He died at the age of 56, in the year 1704.

MERCHANT, a person who buys and sells commodities in gross, or deals in exchange; or that traffics in the way of commerce, either by importation or exportation.

MERCURIALIS ANNUA. *Annual Dog's Mercury.*—Persons who are in the habit of gathering wild herbs to eat, should be careful of this. It grows plentifully in all such grounds, and is common with fat-hen and the other herbs usually collected for such purposes in the spring, and from which it is not readily distinguished; at least, we cannot describe a difference that a person, ignorant of botany, can distinguish it by.

MERCURY, is a metal, which in our climate is always fluid, but in intense cold it becomes solid, and then resembles silver in appearance, and is malleable.—It is sometimes found native, but much more frequently combined with sulphur, when it is denominated cinnabar. It is separated from the sulphur by distillation with quick-lime or iron filings. Mercury is obtained abundantly in the Austrian territories, and in South America: Mercury has a great affinity to other metals. Dip a shilling in mercury, it will be overcast over, and will require to be rubbed very much before the mercury is got off. The same circumstances will occur if any other metal be put in mercury. Rub some quicksilver and tinsell together, and they will enter into one mass. Such a composition is called an amalgam. Mercury and lead will also combine. If lead, bismuth, and mercury, are united together, the amalgam will be equally fluid with the simple mercury itself.—From this circumstance, dishonourable dealers frequently impose on the public this impure composition, and, when the metal is to be used medically, dangerous consequences are the result. Mercury is used in barometers, thermometers, in silvering looking-glasses, and forming amalgams for gilding and silvering metals; also in the making of vermilion. In countries where there are gold and silver mines, it is employed in separating the precious metals from extraneous matter. Mercury is nearly fourteen times the weight of water, and is the heaviest of all metals after gold and platinum. In consequence of its great weight, if a piece of stone, iron, lead, or silver, be put in a cup of mercury, it will float in the same manner, and for exactly the same reason, as a piece of wood in water. Mercury is readily soluble in acids; as may easily be ascertained, and from its very extensive use in medicine, there are innumerable preparations of it, by which it may be exhibited in powders, pills, or drops to the patient. The most usual is calomel, which is a preparation of mercury and mercuric acid. One preparation of mercury, named corrosive sublimate, is a most deadly poison. Mercury will readily unite with sulphur. Melt some sulphur in a crucible on the fire, and then add a little mercury, and stir the whole together.

To Draw a Meridian Line.—Knowing the south quarter pretty nearly, observe the altitude FE of some star on the eastern side thereof, not far from the meridian $HZRN$; then keeping the quadrant firm on its axis, so as the plummet may still cut the same degree, only directing it to the western side of the meridian, wait till you find the star has the same altitude as before $f. e.$ Lastly, bisect the angle Ee , formed by the intersection of the two planes wherein the quadrant is placed at the time of the two observations, by the right line HR . This HR is a meridian line. Or thus: On the horizontal plane, from the same centre C , describe several arcs of circles BA , ba and e , and on the same centre C erect a stile, or gnomon, perpendicular to the plane ACB , a foot or half a foot long. About the 21st of June, between the hours of nine and eleven in the morning, and between one and three in the afternoon, observe the points B, b , &c. A, a , wherein the shadow of the stile terminates. Bisect the arcs AB , ab , &c. in D, d , &c. If then the same right line DE bisect all the arcs AB , ab , &c. it will be the meridian line sought. As it is difficult to determine the extremity of the shadow exactly, it is best to have the stile flat at top, and to drill a little hole, noting the lucid spot projected by it on the arcs AB , and ab , instead of the extremity of the shadow. Otherwise, the circles may be made with yellow, instead of black, &c. Several authors have invented particular instruments and methods for the describing of meridian lines, or rather for determining equal altitudes of the sun in the eastern and western parts of the heavens; but as the former of the methods above delivered suffices for astronomical observations, and the latter for more ordinary occasions, we shall omit giving any descriptions of them.

MERIDIAN Line, on a dial, is the same as the 12 o'clock hour line. *Meridian Line*, on the Gunter's scale, is a line divided unequally towards 87° , corresponding to the meridian in Mercator's chart.

Magnetic MERIDIAN, a great circle passing through the magnetic poles.

MERIDIAN Altitude, the altitude of any of the heavenly bodies when they are upon the meridian.

MERIDIONAL DISTANCE, in Navigation, is of the same import as *DEPARTURE*, or distance between the meridians of two places.

MERIDIONAL Parts, Miles, or Minutes, in Navigation, are the parts of the increased meridians according to the Mercator chart. The parts of the enlarged meridians in the Mercator chart increase in proportion to the cosines of the latitudes to radius, or as the radius to the secants, or since the radius is constant, they increase simply as the secants; and therefore the whole enlarged meridian for any parallel of latitude will be proportional to the sum of all the secants to that place, which, for common purposes, are found near enough by adding together the secants of every angle in minutes; that is,

$$\begin{aligned} \text{for } 1' &= \sec. 1' \\ \text{for } 2' &= \sec. 1' + \sec. 2' \\ \text{for } 3' &= \sec. 1' + \sec. 2' + \sec. 3'. \\ &\text{&c.} \end{aligned}$$

and this way they were first computed by Wright. But it is obvious, that this is merely an approximation, and at the same time attended with considerable labour; other methods have therefore been invented for this purpose by Bond, Gregory, Halley, Robertson, &c. See the latter author's *Treatise on Navigation*, vol. ii. book 8. But if the earth be considered as a spheroid, the method of computation is a little more varied, though it is attended with the same accuracy as in the former case. See Dr. Jamieson's *Treatise on the Construction of Maps*.

MERLIN. See *FALCO*.

MEROPS, a genus of birds of the order plover. *Gmelin* notices twenty-six species, and *Latham* twenty. The common bee-eater, is about ten inches long, and found in many countries of Europe, though never observed in Great Britain. It is particularly fond of bees, but will eat various other insects; many of which it seizes, like the swallow, on the wing. When insects are with difficulty to be found, it feeds on many species of seeds.

MESNE, he who is lord of a manor, and has tenants holding of him, yet himself holds of a superior lord.

MESSE Process, an intermediate process which issues pending the suit, upon some collateral interlocutory matter. Sometimes it is put in contradistinction to final process, or process of execution; and then it signifies all such process as intervenes between the beginning and end of a suit.

MESPILUS, in Botany, a genus of the *Icosandria pentagynia* class and order.—Natural order of pomaceae. There are nine species. The Dutch or common medlar never rises with an upright trunk, but sends out crooked deformed branches, not far from the ground; leaves large, entire, downy, on their under side: flowers very large, as also the fruit, which approaches to the shape of an apple. This tree, bearing the largest fruit, is now generally cultivated: the Nottingham medlar has a more poignant taste, but the fruit is considerably less.

MESSENGERS, are certain officers chiefly employed under the direction of the secretaries of state, and always in readiness to be sent with all kinds of despatches, foreign and domestic. They also, by virtue of the secretaries' warrants, take up persons for high treason, or other offences against the state.

METALLURGY, comprehends the whole art of working metals, from the state of ore to the utensil; hence, assaying, gilding, refining, smelting, &c. are only branches of metallurgy. In a more limited sense, it includes only the operations which are followed in separating metals from their ores.

METALS. Gold occurs in a metallic state, alloyed with a little silver or copper, in the mines of Germany, Hungary, and America, in veins, and disseminated in granite, gneiss, porphyry, and schist; in flakes, massive, and in grains, of a yellow colour, shining, opaque, and of a metallic lustre. Pure gold, chemically obtained, is of a deep yellow colour; it melts at a bright red heat, and, in fusion, appears of a brilliant green; and it forms compounds with most of the gaseous and simple combinations.

Silver occurs in nature pure, and alloyed with gold, antimony, arsenic, and bismuth. Common native silver occurs in veins, in the middle or upper parts when traversing granite, gneiss, mica slate, and porphyry, in primitive mountains; and wacke, in transition ores in Cornwall, Saxony, Hungary, and Mexico; in crystals, massive, and in leaves; of a whitish splendid metallic lustre, and opaque. Auriferous native silver, containing a portion of gold, was formerly found in the mines of Konigsberg, in Norway, and at present in those of Schlangenbergh in Siberia. It melts at a cherry-red heat, in fusion is very brilliant, and is not oxidized by exposure to air.

Platinum is found in small grains and rolled pieces, in alluvial soil, along with gold, silver, osmium, iridium, rhodium, and quartz, in New Grenada and Brazil, of a steel gray colour and shining lustre. This substance is dissolved in nitro-muriatic acid, then precipitated by a solution of carbonate of ammonia; this is repeated, and the second precipitate heated while hot, leaves pure platinum,—a white metal very difficult of fusion, and unaltered by the joint action of heat and air.

Palladium, Rhodium, Iridium, and Osmium, have much resemblance in lustre, and all are obtained from crude platinum; but only the first is malleable.

Mercury occurs rarely in primitive and transition rocks; more frequently in those of the coal formation; in *Deux-Ponts*, *Idria*, and other European mining districts. The principal ore is native cinnabar, whence the mercury is chemically separated. It is a brilliant tin-white metal, with a blue tint/opaque, splendid, and metallic; liquid at all common temperatures.

Copper is found native, and in various states of combination. It occurs in crystals, and massive, in granite, gneiss, mica slate, clay slate, primitive limestone, and serpentine; often in small veins, also in grains, and sometimes in blocks many pounds weight, in alluvial districts; in *Skorpion* in Shetland,

and in the Cornish copper mines. Large masses occur in the northern part of North America. It has a fine red colour, much brilliancy, is very malleable and ductile, has a peculiar smell when warmed or rubbed, and melts at a cherry-red or dull white heat.

Tellurium occurs in wacke in Transylvania, and also in Tellmark in Norway, granular, massive, and disseminated, of a tin-white colour, shining metallic lustre, rather brittle, and easily frangible, fusible, and very volatile.

Iron is of a blue-white colour, very malleable and ductile, and fusible at a white heat. The most important native combinations, whence are drawn the immense supplies for the arts of life, are the oxides. It is combined with sulphur, and several acids; also some vegetable and animal bodies, and is so abundant that few fossils are devoid of it. The different ores are found often in thick beds in the primitive rocks, gneiss, hornblende slate, granite, &c. less in transition rocks, in veins, beds, and masses in porphyry.

Tin has a silvery-white colour, is malleable, but sparingly ductile; it is obtained by heating red with charcoal the native ore, which in all its varieties occurs in granite, gneiss, porphyry, and alluvial deposits, in the Cornish mines, in crystals, and concretions, of various colours, splendid, adamantine lustre; semitransparent to opaque.

Zinc is a bluish-white metal, malleable, but very brittle about the point of fusion, (690°): the ore occurs in New Jersey and Sussex, North America, of a red colour, massive, translucent, and opaque. The oxide occurs in veins of galena, and clay slate, and in beds in masses, in the mines of Flint and Leicestershire; in crystals, and concretions, dull lustre, opaque; when the metal is red, it inflames, burns bright, and is converted into a white tasteless flocculent substance, soluble in alkalies, and called *philosopher's wool*.

Manganese is of a bluish-white colour, very brittle, and difficult of fusion; and becomes an oxide when exposed to the air. The ore is found native in great abundance, in veins in primitive rocks; in crystals and concretions of a grayish-black colour, massive, glimmering, opaque. Manganese of a brown and red colour occurs at Kapala, in Transylvania, and at Catharineberg, in Siberia; and in Sweden, in beds of magnetic iron ore, in gneiss, manganese spar occurs massive, of a bright rose-red colour.

Potassium is a white metal of great lustre; (obtained by decomposing, by the action of iron at a white heat, the substance called caustic potash,) on exposure to air it instantly tarnishes; it is ductile, and of the consistency of soft wax; when cold it is hard and brittle; it easily fuses; heated in air, it burns with a brilliant white flame, and at bright red heat rises in vapour.

Sodium (obtained from soda by a method analogous to that for obtaining potassium) in colour resembles lead, easily fuses, is volatile at a white heat, burns when heated in contact with air, and thrown on water produces violent action, but the metal does not often inflame.

Barytes obtained from an amalgam of the earth baryta and mercury negatively electrized; and the mercury then expelled by heat, leaves the metal, of a dark gray colour, more than twice the weight of water; it greedily absorbs oxygen, and gently heated burns with a deep red light.

Lead occurs in galena veins at Leadhills, Wanlockhead, and the Paris mine in Angles, in crystals, granular and massive, of a bluish-white colour mostly, adamantine lustre, from splendid to shining, and translucent; and convertible into an oxide by the united action of heat and air.

Nickel occurs native in Scotland, at Leadhills, and Wanlockhead, and in the Coal-field of West Lothian; it occurs in silver and cobalt veins in gneiss, mica slate, clay slate, and sienite; also in bituminous marl slate, granular, massive; brittle, copper-red, shining, and metallic lustre.

Antimony exists in nature nearly pure, in the mines of Germany, Norway, Russia, and France, and frequently occurs, combined with other metallic substances, in metalliferous veins, where they cross each other, in gneiss, mica slate, clay slate, and porphyry, massive, in plates, of a tin-white colour, soon tarnishing; glistering metallic lustre; it is very inflammable, fusible, and volatile, and highly poisonous.

Molybdenum is of a whitish-gray colour, and with extreme difficulty fused.

Chrome ore occurs in veins and beds in serpentine and trap, in Scotland and Shetland, in crystals and granular, grayish, shining, and opaque; the metal is white, brittle, and of very difficult fusion.

Tungsten is a native tung state of lime, and Wolfram is the same of tungstic acid, iron, and manganese. They occur in Cornwall, sometimes in crystals, granular, massive; of a white, brown, and yellow colour, shining and splendid, resinous, translucent; the metals in colour resemble iron, are hard and brittle.

Columbium was first discovered by Mr. Hatchett in a mineral from North America. Little is yet known of its properties.

Strontian is procured from the earth strontia, by the same process as Barium; which metal it much resembles; but it is not poisonous.

Uranium. The oxide of sulphuret occurs native in the mines of Cornwall, in crystals, green, splendid, and translucent; hence the metal is obtained of a gray colour, and with difficulty fused.

Cerium is obtained from a mineral named Cesite, which occurs in a bed of copper at Ridderhyttan, in Sweden.

Cobalt is of a gray colour, brittle, and difficult of fusion, obtained by a very complex process from the ores, which occur at various places in Norway, Sweden, and Britain.

Bismuth is a brittle, brilliant white metal, with a slight tint of red; not easily fused, and on cooling always crystallizes; is affected by heat and air. With gold, platinum, and tin, it forms brittle compounds.

Calcium is a white metal, obtained (like Barium,) from lime; which, exposed to air, and gently heated, burns in a whitish flame.

Of numerous new minerals we select the following from Dr. Brewster's Edinburgh Journal of Science for 1825:

Roselite, a new mineral, of a deep red rose colour, contains water, oxide of cobalt, lime, arsenic acid, and magnesia.

Columbite, from America, contains 30 per cent. of manganese.

Brochantite, of an emerald green colour, is met with in massive red copper, from the Bank mine, Ekatherineburg, Siberia. Fluellite, compounded of alumina and fluoric acid, is whitish and prismatic.

Torrelite, from America, is composed of silica, lime, and iron.

Hyalosiderite, a new mineral, occurs in small crystals, sometimes imperfectly formed, in a basaltic amygdaloid of a reddish-brown colour, at Breisgaw, in Germany. This is a species of *volcanic iron glass*; magnetic if gently heated, and fusible in a high temperature. Specific gravity = 2.875.

Hopeite, a new mineral, prismatic in form, grayish-white in colour, and translucent. Specific gravity = 2.76. It is soluble in acids, without effervescence. It is found near Aix-la-Chapelle.

Childrenite, a new mineral, whose hardness is so great that it scratches glass, and is found near Tavistock in Devonshire, on the surface of quartz. Its constituent parts are iron and alumina, and it resembles in appearance sparry iron ore and heavy spar.

Somervillite, a new mineral, of a pale yellow, hard and fusible into greenish globules. It is found about Vesuvius.

Nuttallite, a new mineral, found imbedded in calcareous spar, soft, and glassy in its fracture. Of American origin.

Babingtonite, a new mineral, brilliant, black, scratches glass, and is composed of iron, silica, and manganese.

Sillimanite, a new mineral, occurs crystallized, dark-gray colour, brilliant upon the single face of cleavage, harder than topaz, brittle and easily reduced to powder; specific gravity = 3.410. It is met with in Connecticut.

Baryto-Calcite, a new mineral, of a grayish tinge; specific gravity = 3.66; it consists of carbonate of barytes and carbonate of lime, with traces of iron and manganese.

METAMORPHOSIS, the change of a person or thing into another form. Most of the ancient metamorphoses include some allegorical meaning, relating either to physics or morality. Some authors are of opinion, that a great part of the ancient philosophy is couched under them.

METAPHOR, the application of a word to a use to which in its original import it cannot be put, as "he bridges his anger," "the golden harvest."

METAPHYSICS, the sciences which consider beings as abstracted from all matter, particularly beings purely spiritual, as God, angels, the human soul; or it may be defined, the science of the principles and causes of all things existing. Hence it is, that mind or intelligence, and especially the supreme intelligence, which is the cause of the universe, and of every thing which it contains, is the principal subject of this science. The word originated with Aristotle, who has termed a treatise which chiefly relates to the intellectual world, and which is placed after his physics, (*see* PHYSICS,) *METAPHYSICA*. So that it may mean either something "beyond physics," or merely "an appendix to physics," or natural history.

METEMPSYCHOSIS, from *meta*, again, *em*, in, and *psyché*, the soul. Transmigration, or the supposed passage of the soul from one body to another. Pythagoras and his followers believed that after death men's souls passed into other bodies, of this or that kind, according to the manner of life they had led. If they had been vicious, they were imprisoned in the bodies of miserable beasts, there to do penance for several ages, at the expiration whereof they returned afresh to animate men. But if they lived virtuously, some happier brutes, or even a human creature, was to be their lot. Pythagoras is supposed to have borrowed this from the ancient Brachmans, (certain inhabitants of India.) The notion still makes the principal foundation of their religion. Many not only forbear eating any thing which has life, but even refuse to defend themselves from wild beasts.

METEOR. This term is by some writers made to comprehend all the visible phenomena of meteorology, but it is more generally confined to luminous bodies, appearing suddenly at uncertain times, and with more or less of motion in the atmosphere. These may be reduced under three classes, viz. fire balls, falling or shooting stars, and ignes fatui. In tropical climates these meteors are more common and more stupendous than in these more temperate regions. But they sometimes also visit the more genial regions of Europe. Two of them appeared in England in the year 1783, the first of them was seen on the 18th of August, and was, in appearance, a luminous ball, which rose in the N. N. W. nearly round; it however soon became elliptical, and gradually assumed a tail as it ascended, and in a certain part of its course, seemed to burst, after which it proceeded no longer as an entire mass, but was apparently divided into a cluster of balls of different magnitudes, and all carrying or leaving a train behind, till having passed the east, and verging considerably to the south, it gradually descended, and was lost out of sight. The time of its appearance was about sixteen minutes past nine in the evening, and it was visible about half a minute. It was seen in all parts of Great Britain, at Paris, at Naples, in Burgundy, and even at Rome; and is supposed to have described a tract of 1000 miles at least over the surface of the earth. The diminution of these meteors is often so great as to totally obliterate the stars, to make the moon look dull, and even to affect the spectators like the sun itself. The body of the fire ball, even before it bursts, did not appear of a uniform brightness, but consisted of lead and dull parts, which were constantly changing their respective positions, so that the whole effect was like an internal agitation or boiling of the matter. Its height seems to have varied from 50 to 60 miles. A report was heard some time after the meteor disappeared, and this report was loudest in Lincolnshire and the adjacent parts, and again in the eastern parts of Kent. Judging from the height of the meteor, its bulk is conjectured to have been not less than half a mile in diameter; and when we consider this bulk, its velocity cannot fail to astonish us, which is supposed to be at the rate of more than 40 miles in a second.

Dr. Blagden is of opinion, that the general cause of these phenomena is electricity; but we cannot subscribe to this opinion. The duration of the fire-ball, the unequal consistency of the mass, and several other points in the narration, seem to indicate that its materials were of a less rare and evanescent nature than the electric fire.

The shooting or falling star is a common phenomenon; but

though so frequently observed, the great distance and transient nature of these meteors have hitherto frustrated every attempt to ascertain their cause. The connexion of these with an active state of the atmospheric electricity, is, however, certain from observation; and we have more reason to consider them as electric scintillæ than as solid or fluid matter in the act of combustion. They precede a change of wind. Concerning the nature and composition of the *ignis fatuus*, or will-o'-the-wisp, there is less dispute, the generality of philosophers being agreed, that it is caused by some volatile vapour of the phosphoric kind, probably the phosphorised hydrogen gas. The light from putrescent substances, particularly putrid fish, and those sparks emitted from the sea or sea-water when agitated, in the dark, correspond in appearance with this meteor.

METEORIC STONES. *See* AEROLITES.

METEOROLOGY, the application of natural philosophy to the constant or variable phenomena going on in the mass of the atmosphere, or at the surface of the earth, by the general action of natural agents, such as heat, electricity, and magnetism. In it are comprehended the unequal distribution of heat upon the earth, the laws of its variations in the different seasons of the year, the decrease of density, and the falling of the temperature of the atmospheric strata at different heights, winds, clouds, fogs, rain, snow, hail, thunder, and water-spouts.

The leading facts respecting Meteorology are summed up by Mr. Daniell in the following propositions.—1. The mean height of the barometer at the level of the sea is the same in every part of the globe. 2. The barometer constantly descends in a geometrical progression, for equal ascents in the atmosphere, subject to a correction for the decreasing temperature of the elevation. 3. The mean temperature of the earth's surface increases gradually from the poles to the equator. 4. The mean temperature of the atmosphere decreases from below upwards in a regular gradation. The fact is sufficiently established by numerous observations. Mr. Dalton was the first to demonstrate the natural equilibrium of heat in an atmosphere, is when an atom of air, in the same perpendicular column, is possessed of the same quantity of heat, and consequently that an equilibrium results when the temperature gradually diminishes in ascending. This is the natural consequence of the increased capacity for heat derived from rarefaction, when the quantity of heat is limited, the temperature must be regulated by the density.

5. The barometer at the level of the sea is but very slightly affected by the annual or diurnal fluctuations of temperature. 6. The barometer in the higher regions of the atmosphere is greatly affected by the annual or diurnal fluctuations of temperature. This observation is easily confirmed in various ways, but it is sufficient to refer for its correctness to those valuable registers which are simultaneously kept at Geneva, and the summit of Mount St. Bernard.

7. The heating and cooling of the atmosphere by the changes of day and night take place equally throughout its mass. This is fully established by the same series of observations. 8. The average quantity of vapour in the atmosphere decreases from below upwards, and from the equator to the poles. This consequence is obviously derivable from the preceding laws of temperature, and is moreover amply confirmed by experiment. 9. The condensation of elastic vapour into cloud raises the temperature of the air. In confirmation of this theoretical and practical conclusion, the observation of M. de Luc may be adduced.

10. Another remarkable phenomenon is, that there exists a general tendency in the wind to blow from north to east, and south-east towards the equator in latitudes below 30°. 11. While the trade wind blows upon the surface of the earth, a current flows in the contrary direction at a great elevation in the atmosphere. This necessary consequence of the theory of the trade winds, rested for a long time upon theoretical conclusions only, as the eruption, however, of the volcano in the island of St. Vincent, in the year 1812, placed the fact beyond dispute. The island of Barbadoes is situated considerably to the east of St. Vincent, and between the two the trade wind continually blows, and with such force that it is with considerable difficulty, and only by making a very long circuit, that a ship can sail from the latter to the former; notwithstanding this, during the summer

tion at St. Vincent, dense clouds were formed at a great height in the atmosphere above Barbadoes, and a vast profusion of ashes fell upon the island. This apparent transportation of matter against the wind caused the utmost astonishment amongst the inhabitants, and the certainty of the fact cannot but be considered as of the utmost interest to the science of meteorology.

12. The mean height of the barometer is not affected by the trade winds. This is a proof that the quantity of air which passes below from the poles to the equator, must be exactly balanced by an equal quantity flowing above in the opposite direction. 13. Between the latitudes 30° and 40° both in the northern and southern hemispheres, westerly winds prevail. 14. The western coasts of the extratropical continents have a much higher mean temperature than the eastern coasts. This difference is extremely striking between the western coasts of North America, and the opposite eastern coast of Asia. It is explained by the heat evolved in the condensation of vapour swept from the surface of the ocean by the western winds. This general current in its passage over the land deposits more and more of its aqueous particles, and by the time that it arrives upon the eastern coasts is extremely dry; as it moves onwards it leaves behind it the humid atmosphere of the intermediate seas, and arrives upon the opposite shores in a state of saturation. Great part of the vapour is there at once precipitated, and the temperature of the climate raised by the evolution of its latent heat.

15. A wind generally sets from the sea to the land during the day, and from the land to the sea during the night, especially in hot climates. The land and sea breezes are amongst the most constant of the phenomena of the inconstant subject with which we are occupied; the land becomes much more heated by the action of the sun's rays than the adjacent water; and the incumbent atmosphere is proportionably rarefied; during the day, therefore, the dense air of the ocean rushes to displace that of the land; at night, on the contrary, the deep water cools much more slowly than the land, and the reverse action takes place as these changes proceed gradually. The height of the barometer is not affected by them.

16. The trade winds in the neighbourhood of the western coasts of the large continents, in their course have their direction changed. This is an effect of the same nature as that of the land and sea breezes. Those parts of Africa and America which lie between the tropics, become intensely heated by the action of a vertical sun: the columns of the atmosphere which rest upon them must therefore be highly rarefied, and the more temperate air of the surrounding seas will press upon them. This influence is so decided as to overcome the tendency of the east wind; and on the western coasts of both continents a wind from the west prevails. This is again an instance of a complete perpendicular change from a permanent cause, and the total pressure is unaffected. Of the same nature are the monsoons of the Indian ocean, and other periodical winds; they are occasioned by a particular distribution of land and water, acted upon by the periodical changes of the sun's declination. While the sun is vertical to the place where they occur, the land becomes heated, and the air expanded, and the wind flows towards the coasts as the sun retires towards the opposite point of its course; the land cools faster than the surrounding seas, and the course of the wind is westward, the simplest way of regarding the sun's motion in declination, as affecting the temperature of the various latitudes, is to suppose a motion of the whole system; by which the line of greatest heat, and the two points of greatest cold, maintaining their relative distances, vibrate on either side of the earth's equator and poles. None of these changes affect the barometer.

17. Rain seldom occurs in the constant trade-winds, but abundantly and constantly in the adjoining latitudes. Between the tropics the elasticity of the aqueous vapour reaches its maximum amount, and within these limits only, rises to any extent into the upper part of the atmosphere. Its own force which is laterally exerted, is assisted by the equatorial wind, and it flows to the north and south as fast as it rises within the zone; no accumulation can therefore be formed, and the temperature being remarkably steady, seldom varying more than one or two degrees, precipitation can but seldom occur. The

continental parts, however, of the same regions being liable to greater vicissitudes of heat, are subject to rainy seasons, which are periodical, like the monsoons of the same climates, and are governed as they are by the progress of the sun in declination. The condensation, while it lasts, is in proportion to the density of the vapours, and is violent beyond any thing that is known in temperate climates. The alternate seasons of fine weather are distinguished by cloudless skies and perfect serenity. The extra tropical latitudes, on the contrary, beyond the bounds of the trade winds, are at all times exposed to great precipitation; the vapour in its course is subjected to a rapidly decreasing temperature, and the condensation is fed by a constant supply. We are thus led to the consideration of a temperate zone and a variable climate.

18. Between the tropics the fluctuations of the barometer do not much exceed $\frac{1}{4}$ of an inch, while beyond this space they reach to three inches. 19. In the temperate climates the rains and the winds are variable. 20. As we advance towards the polar regions we find the irregularities of the wind increased; and storms and calms repeatedly alternate, without warning or progression. The extremes of heat and cold will sometimes prevail within a very limited compass; and forcible winds will blow in one place, when at the distance of a few leagues gentle breezes prevail. Ships within the circle of the horizon may be seen enduring every variety of wind and weather at the same moment: some under close-reefed top-sails labouring under the force of a storm; some becalmed, and tossing about by the violence of the waves, and others lying under gentle breezes, from quarters as diverse as the cardinal points. The fluctuations of the barometer are also great and sudden, proving that theory would have induced us to conclude that the irregularities of those regions extend to the higher strata of the atmosphere.

21. In the extra tropical climates, a fall in the barometer almost always precedes a fall of rain, and indicates an acceleration or change of the aerial currents. 22. Barometers situated at great distances from each other often rise and fall together with great regularity. 23. More than two currents may often be traced in the atmosphere at one time by the motions of the clouds, &c. 24. The force of the winds does not always decrease as the elevation increases, but on the contrary is often found to augment rapidly. 25. The variations of the barometer are less in high situations than in those at the level of the sea. 26. In Great Britain, upon an average of ten years, westerly winds exceed the easterly in the proportion of 225 to 140. Of those from the east, the northerly exceed the southerly in the proportion of about 74 to 64; leaving but a very small proportion indeed which blow from the most irregular point, viz. the south-east.

27. Upon the same average the northerly winds are to the southerly, 192 to 173. 28. Northerly winds almost invariably raise the barometer, while southerly ones constantly depress it. 29. The most permanent rains of this climate come from the southern regions. 30. The mean height of the barometer varies but little with the changes of the seasons. 31. The elasticity of the aqueous vapour does not decrease gradually as we ascend in the atmosphere, in proportion to the gradual decrease of the temperature and density of air; but the dew point remains stationary to great heights, and then suddenly falls to a large amount. 32. The tension of vapour given off in the process of evaporation is determined, not by the temperature of the evaporating surface, but by the elasticity of the aqueous atmosphere already existing. 33. The apparent permanency and stationary aspect of a cloud is often an optical deception arising from the solution of moisture on one side of a given point, as it is precipitated on the other. 34. The quantity of vapour in the atmosphere, in the different seasons of the year, (measured on the surface of the earth, and near the level of the sea,) follows the progress of the mean temperature. 35. The pressure of the aqueous atmosphere separated from that of the aerial, generally exhibits changes directly opposite to the latter. 36. Great falls of the barometer are generally accompanied by a temperature above the mean for the season, and great rises by one below the same. That the different phases of the moon have some connexion with changes in the atmosphere, is an opinion so universal and popular, as to be on that account alone entitled to attention. No observation is more general, and on no occa-

principle of operation is the same, which is, that it moves a fine wire parallel to itself, in the plane of the picture of an object, formed in the focus of the telescope; and with such accuracy as to measure with the greatest precision its perpendicular distance from a fixed wire in the same plane, by which means the apparent diameters of the planets, and other small angles, are exactly determined. This may be illustrated as follows:—Let a planet be viewed through a telescope, and when the parallel wires are opened to such a distance as to appear to touch exactly the two opposite extremities of the disc of the planet, it is obvious that the perpendicular distance between the wires is then equal to the diameter of the object in the focus of the object-glass.

Let this distance, whose measure is given by the mechanism of the micrometer, be represented by the line pq ; then, since the measure of the focal distance qL may be also known, the ratio of qL to pq , that is, of radius to the tangent of the angle qLp , will give the angle itself by a table of sines and tangents; and this angle is equal to the opposite angle PLQ , which the real diameter of the planet subtends at L , or at the naked eye. This is the general principle on which the construction of this instrument depends, and the different forms that have been given to it have been more directed towards an improvement of the mechanism than to any other object, but our limits will not allow of entering into a detail of these constructions, and we shall therefore confine our remarks to a description of the divided object-glass micrometer, as invented by Dollond, and allowed to be the most accurate of any yet discovered.

Divided Object-Glass Micrometer. This instrument consists of a convex lens divided into two equal parts C, D , by a plane which passes through its axis; and the segments are movable on a graduated line CD , perpendicular to that axis. Let C, D , be the centre of the segments, and P, Q , two remote objects, images of which will be formed in the lines PCE , QDE , and also in the principal foci of the segments. Let the glasses be moved till these images coincide as at E ; then

the angle PEQ , which the objects subtend at E the principal focus of C , or D , is equal to the angle which CD , the distance of the centres, subtends at the same point; and therefore, by measuring this angle, we may determine the angular distance of the bodies P and Q , as seen from E . Draw EG perpendicular to CD ; and, because the triangle CEG is isosceles, $CG = GD$, and the $\angle CEG = \angle GED$; also, GD is the sine of the angle GED , to the radius ED ; therefore, knowing ED and GD , the angle GED may be found by the tables; and consequently $2GED$, or CEG , may be determined. The angle CEG is in general so small, that it may, without sensible error, be considered as proportional to the subtense GD . And being determined in one case by observation, it may be found in any other by a single proportion. If the objects be at a given finite distance, the angle PEQ will still be proportional to CD ; for on this supposition, the distance CE , or DE , of either image from the corresponding glass, will be invariable; therefore the angle CEG will be proportional to GD . The divided object-glass is applied both to reflecting and refracting telescopes; and thus small angular distances in the heavens are measured with great accuracy.

MICROPHONICS, the science of magnifying small sounds. **MICROSCOPE**, an instrument for magnifying small objects by means of a proper adjustment and combination of lenses or mirrors. The invention of microscopes, like most other ingenious discoveries, has been claimed for different authors. Huygens informs us, that the first microscopes were constructed by Drebbel, a Dutchman, in 1621; but F. Fontana, a Neapolitan, in 1646, claims the invention as his own, which he dates from the year 1618. Microscopes are divided into *single*, *compound*, *reflecting*, *solar*, &c.

Single or Simple Microscope, is one which consists of a single lens.

Theory of Single Microscopes.—If the angle which subtends at the centre of the eye, when at a proper distance for distinct vision, be less than a certain limit, that is, if it be less than $4'$, it will only appear to the eye like a physical point; and if we endeavour to increase the image by bringing it nearer to the eye, the extreme rays will diverge so much as to render the object indistinct; and if the extreme rays be sloped, there will then be too little light to make the object distinctly visible; the microscope is, therefore, introduced in order to supply these defects of natural vision, which is effected by placing the object in the principal focus of a glass spherule or lens, whose focal length is short; in which case it may be distinctly seen, the visual angle, as well as the quantity of light admitted into the eye, being increased, and the parts which before appeared only as a physical point, may now be subjected to examination; the visual angle thus formed, being to that formed at the naked eye, at the least distance of distinct vision, as that distance is to the focal length of the glass.

Let QP be an object placed in the principal focus of the lens, or spherule AE , whose centre is B ; LQ the least distance at which it can be seen distinctly with the naked eye; join LP, PE . Then the angle under which the object is seen through the glass, is equal to PCQ ; and the angle under which it is seen with the naked eye, is QLE . Also, when these angles are small, since they have a common subtense QP , they are nearly in the inverse ratio of the radii BQ, LQ ; that is, the visual angle, when the object is seen through the glass: the visual angle when it is seen with the naked eye at the distance $LQ :: LQ : BQ$.

Example. If the focal length of the glass be $\frac{1}{4}$ of an inch, and at the least distance of distinct vision 8 inches, the visual angle of the object when viewed through the glass : is the visual angle when it is seen with the naked eye :: $8 : \frac{1}{4} :: 400 : 1$.

The **Double or Compound Microscope**, consists of two lenses at least, but generally of three, and often more. We shall first describe the one which contains two:—The lens DE , in fig. 1, (plate OPTICS,) is therefore to be overlooked in comparing this description with the figure. The first or smallest lens C is placed near the small object AB , at a little more than its focal distance from it; a large image of the object is thus formed, which will be as much larger than the object, as the distance CL is greater than the distance AC ; and as this distance may be made greater or less by placing the object nearer to or farther from the lens C , the image may be increased or diminished at pleasure. And as this image may be distinctly viewed, and still further magnified by a convex lens MN , placed at its focal distance from the image, it is evident that small objects may be thus magnified to many times their real size.* Suppose, for example, that the distance of the object CL is 12 times the distance of the image at CA , then will the length of the image KL be 12 times the length of the object AB , when viewed with the naked eye; but this length of the image, if viewed with an eye-glass of one inch focal distance, will appear six times as large as if does

* This lens or glass being nearest the eye, is usually called the eye-glass.

to the naked eye, and therefore its length will appear 12 times 6, or 72 times larger than to the naked eye; and, as its breadth will be magnified in the same proportion, its surface will be 72 times 72, or 5184 times larger than that of the object when viewed with the naked eye. Though the magnifying power of this microscope be very considerable, yet the extent or field of view is very small and confined; therefore, in order to enlarge it, and to increase the quantity of light, another large lens D E, is placed between the two already noticed, (see the figure,) by which means the angle D C E or A C B, under which the visible part of the object appears, may be considerably enlarged; the image will then be formed again at F G, and as the image thus formed is now contained between the two extreme parallel rays of the eye-glass M F and N G, is wholly visible; whereas before, the part O Q could only be seen. But though the object is not quite so much magnified on the whole, in this as in the former case, yet the visible surface is very much increased by the addition of this third glass. The glass R S is a plain mirror, which is employed to reflect the light I, in order to illuminate transparent objects when examined by this instrument.

The Solar Microscope, invented by Dr. Lieberkhan, is employed to represent very small objects on a very large scale, in a dark room. This is accomplished in the following manner: Let A B, fig. 2, plate OPTICS, represent a beam of the sun's light falling on a small mirror or looking-glass D C, adjusted by two brass wheels to such an inclination as shall reflect the rays which fall upon it parallel to the horizon, to a large convex lens E F, which converges them to a focus; near this focus, as at G H, is placed a small object, which is by this means strongly illuminated, and the rays which flow from it through a small convex lens I, so adjusted by a slider to a little more than its focal distance from the object, produce a very large image K L, which being received upon a white table cloth, or allowed to fall on the opposite wall of the darkened room, will represent the object magnified in proportion to the distance of the picture from the lens I.* Suppose that the small lens I is one-tenth of an inch distant from the object, when the image K L is duly formed on a sheet or table cloth, at the distance of 16 feet from the small lens just mentioned; then in 16 feet there are 192 inches, and consequently 1,920 tenths of an inch; therefore the image is 1,920 times the length of the object, and as many times its breadth; the area or surface of the image is therefore 1,920 times 1,920, or 3,686,400 times that of the object. Such is the prodigious magnifying power of the solar microscope.

Harris's Improved Botanic Microscope.—This compact instrument is found particularly to recommend itself to the practical botanist and naturalist, as a truly able assistant in their researches through the animal, vegetable, and mineral kingdoms, and more especially when its facility of management and portability, combined with its extent of magnifying power, are brought into consideration. To use this microscope, fig. 3, plate OPTICS, take its parts out of the case, unscrew the pillar A on the top, the stage B has a stem which attaches at the socket D. The three lenses at E screw into the arm C, which is fixed by the milled head F; that lens which is dotted thus ... magnifies the least, and the lens . the most; and by screwing into each other, seven different magnifying powers are obtained by combination: W is a yet stronger power than those at E, (which must be removed while W is in use,) being for the purpose of observing objects otherwise too minute to be seen. Transparent objects similar to those in slide Y, are examined by attaching them to the stage B, and by varying the inclinations of the mirror G, (which must be towards the light,) the objects will have more or less light reflected on them, and by adjusting the stage B up or down by the rackwork at H, the objects are seen more or less distinctly. When opaque objects are to be examined, remove the mirror G from its box, and screw the lens ... into the back, then fixing it by its stem to the stage B, the light of a candle is concentrated on the objects; this is

* It is scarcely necessary to remark, that the lenses and object to be viewed are placed in a tube, which is screwed into a hole in the window shutter, or a board placed in the window, which serves at the same time to exclude the light.

useless by day. I is a black and white piece on which opaque objects are placed, and fits the stage B. J is a screw box for confining living objects, and is also to be laid on the stage B. K a pair of steel nippers that attaches to the stage B by its stem, for holding small insects, leaves, or wings, &c. L is a pair of forceps for taking up objects too small for the touch. M and N a dissecting knife and point for separating the smaller parts of flowers, &c. The dotted outlines N represent a body that may be screwed on at E, making it an improved Compound Microscope, affording a much larger field of view, and requires a larger case.

MICROSCOPIC OBJECTS, those things which are too small to be seen distinctly by the naked eye.

MIDDLE LATITUDE, is half the sum of two given latitudes when they are both in the same hemisphere, or half their difference if they are in different hemispheres; in which latter case it will always be of the same name as the greater.

MIDWIFERY, in the restricted sense of the word, is the art of assisting women in childbirth. It is generally, however, made to comprehend the management of women, both previously to, and sometime after, delivery; as well as the treatment of the infant in its early state.

MIGRATION OF BIRDS. It has been generally believed, that many different kinds of birds annually pass from one country to another, and spend the summer or the winter where it is most agreeable to them; and that even the birds of our own island will seek the most distant southern regions of Africa, when directed by a peculiar instinct to leave their own country. It has long been an opinion pretty generally received, that swallows reside during the winter season in the warm southern regions; and Mr. Adanson particularly relates his having seen them at Senegal, when they were obliged to leave this country. But besides the swallows, Mr. Pennant enumerates many other birds which migrate from Britain at different times of the year, and are then to be found in other countries; after which they again leave these countries, and return to Britain. The reason of those migrations he supposes to be a defect of food at certain seasons of the year, or the want of a secure asylum from the persecution of man during the time of courtship, incubation, and nutrition.

Water Fowl.—Of the vast variety of water fowl that frequent Great Britain, it is amazing to reflect how few are known to breed here: the cause that principally urges them to leave this country seems to be not merely the want of food, but the desire of a secure retreat. Our country is too populous for birds so shy and so timid as the bulk of these are: when great part of our island was a mere waste, a tract of woods and fens, doubtless many species of birds (which at this time migrate) remained in security throughout the year. Egrets, a species of heron, now scarcely known in this island, were in former times in prodigious plenty; and the crane, that has totally forsaken this country, bred familiarly in our marshes; their place of incubation, as well as of all other cloven-footed water fowl, (the heron excepted,) being on the ground, and exposed to every one. As rural economy increased in this country, these animals were more and more disturbed; at length, by a series of alarms, they were necessitated to seek, during the summer, some lonely safe habitation. On the contrary, those that build or lay in the almost inaccessible rocks that impend over the British seas, breed there still in vast numbers, having little to fear from the approach of mankind; the only disturbance they meet, in general, being from the desperate attempts of some few to get their eggs.

MILDEW, is said to be a kind of thick, clammy, sweet juice, exhaled from or falling down upon the leaves and blossoms of plants. By its thickness and clamminess it prevents perspiration, and hinders the growth of the plant. It sometimes rests on the leaves of trees in form of a fatty juice, and sometimes on the ears of corn. It is naturally very tough and viscous, and becomes still more so by the sun's heat exhaling its more fluid parts; by which means the young ears of corn are so daubed over, that they can never arrive at their full growth. Bearded wheat is less subject to the mildew than the common sort; and it is observed, that newly dunged lands are more liable to mildew than others. The best remedy is a smart shower of rain, and immediately afterwards a brisk wind.

If the mildew is seen before the sun has much power, it has been recommended to send two men into the field with a long cord, each holding one end; and drawing this along the field through the ears, the dew will be dislodged from them before the heat of the sun is able to dry it to that viscid state in which it does the mischief. Some also say, that lands which have for many years been subject to mildews, have been cured of it by sowing seed along with the corn, or immediately after it.

MILE, (*MILLE PASSUS*), a measure of length or distance, containing eight furlongs, &c. See **MEASURE**. The English statute mile is fourscore chains, or 1760 yards; that is, 5280 feet. See **CHAIN**, **YARD**, AND **FOOT**. We shall here give a table of the miles in use among the principal nations of Europe, in geometrical paces, 66,000 of which make a degree of the equator.

	<i>Geometrical paces, yards.</i>	
Mile of Russia,	750	or 1100
of Italy,	1000	or 1467
of England,	1250	or 1760
of Scotland and Ireland,	1500	or 2200
The small league,	2000	or 2933
The mean league,	2500	or 3666
The great league of France,	3000	or 4400
Mile of Poland,	3000	or 4400
of Spain,	3248	or 5028
of Germany,	4000	or 5866
of Sweden,	5000	or 7233
of Denmark,	5000	or 7233
of Hungary,	6000	or 8800

MILARY FEVER, a malignant fever so called from the eruption of certain pustules resembling millet-seeds.

MILITARY TACTICS teach the art of disposing forces in battle array, and performing its proper motions and evolutions. The Greeks, skilful in this part of the military art, had public professors of it, called *Tactici*, who taught and instructed their youth. *Tactics* signifies also the art of inventing and making machines for throwing darts, arrows, stones, fire-balls, &c. by means of slings, bows, and counterpoises. Naval tactics instruct us in the arrangement of a fleet for an engagement by sea.

MILITARY DISCIPLINE, or the training of the soldiers, and the enforcement of the laws and regulations instituted by authority, may be considered the soul of all armies; unless it be established with prudence, and supported with resolution, assemblies of armed men are little better than a rabble, and more dangerous to a state than its enemies. By the force of discipline, men are kept in obedience to command, in opposition to the impulse of their passions, and make each army, as it were, a complicated, but immense and energetic machine.

RANK, is the appointment of officers, or a gradation of authority necessary towards the establishment of discipline and subordination. An army is commanded by a captain-general or commander-in-chief, and general and staff officers. Field-marshal, long disused in the British army, have been revived in the persons of their Royal Highnesses the Duke of York and the Prince of Cobourg; the Duke of Wellington, &c. The rank of commander-in-chief corresponds to the degree of field-marshal in the French service. A lieutenant, or even a major-general, has sometimes the appointment of commander-in-chief. When an army is considerable, the following is deemed an adequate staff, exclusive of the commander-in-chief: a general for the horse and one for the foot, or a general for each wing of the army; a major-general for every two brigades; and nearly half that number of lieutenant-generals. But the duties of all these are much the same; the terms denoting chiefly the gradations of rank. General-officers may command any number of men, from a company or troop to several regiments. Generals have no pay, except when employed; but then they have from ten to twenty pounds a day.

The commander-in-chief, or captain-general, or general, commands all the military of a nation or army; he receives himself his orders from the king, and communicates them to all general-officers, who distribute them through all the corps of the army. Colonels command regiments—but there are lieutenant-colonels, who are the second officers in regiments, and command in the absence of the colonels. The major-general

acts immediately under the general, receiving his orders, and delivering them out to the majors of brigades, with whom he concertes what troops are for duty or guard, detachments, convoys, or foraging parties. The major of a regiment conveys all orders to the regiment after he has drawn them up, sees it march, provides quarters, &c. He is the only officer of an infantry regiment who is allowed a horse in service, to facilitate communications. In a regiment of horse, the major commands in the colonel's absence. A brigadier commands a brigade; and the eldest colonels are usually such as are advanced to this post. Whoever is upon duty is brigadier of the day. He marches at the head of his own brigade, and is allowed a sergeant and ten men of his own brigade, for his guard. The rank of a brigadier general in the British service used to be suppressed in time of peace. Brigadiers, or sub-brigadiers, are posts in the horse-guards. The brigadier, or brigadier-general, appoints an officer called a brigade major, to assist him in all the management of his brigade. Experienced captains are appointed to this post; and act in the brigade as major-generals do in the army, receiving their orders from their commanders.

CAPTAINS. A captain-general is he who commands in chief. A captain of a troop, or company, commands a troop of horse, or company of foot, under a colonel. His duty is, to be careful to keep his company full of able-bodied soldiers; to visit their tents or lodgings; to see what is wanting; to pay them well; and keep them neat and clean. He has the power, in his own company, of making sergeants and corporals. In the horse and foot guards, the captains have the rank of colonels. The commissioned officers, subordinate to the captain, are the lieutenants and ensigns, commonly called subaltern officers. These, though their rank is not the same, perform duty together without distinction. Their ordinary duties are, in garrison, guards, detachments, courts martial, the visiting of hospitals and barracks, fatigues on working parties, and orderly duties. And no officer can exchange his duty with another, except by permission of the commanding officer. Thus, the ensign bears the colours, and has charge of them in battle, yet is he under the lieutenant. The adjutant assists the major, and receives his orders nightly from the brigade major; these, after being submitted to the colonel, he delivers to the sergeants. Almost all duties are regulated by the adjutant as major's assistant, as detachments, guards, the charge of ammunition, the prices of bread, beer, &c. The quarter-master is rather a civil than a military officer; and though next to the adjutant, he has nothing to do with the discipline of the regiment. He superintends the clothing, quarters, ammunition, firing, &c. The surgeon, a commissioned officer on the staff of the regiment, requires to be skilled in physic, pharmacy, and anatomy. The chaplain, the last commissioned officer on the staff, is generally allowed to act by deputy when he thinks proper. Serjeant-major, the first, and properly speaking the only non-commissioned officer on the staff, bears the same subordinate relation to the adjutant, as the adjutant does to the commanding officer; and as the adjutant keeps a register of the officers, so does the serjeant-major of the sergeants and corporals, whom he warns in turn for duty, and orders the quota of men each company is to furnish. The serjeant-major attends all parades, to see if the exact number of men are there, and that they are clean and well dressed. He is to make the other sergeants and corporals responsible for neglect in any of those particulars. Sergeants and corporals are also non-commissioned officers, and superintend the private men; the drum major, the drum boys, and the private men, are mighty in their collective force in an army.

MILUM, *MILLET*, a genus of the *digynia* order, in the triandria class of plants; and in the natural method ranking under the fourth order, graminæ. There are twelve species, of which the most remarkable is the effusum, or common millet.

MILK, a well-known fluid, prepared by nature in the breasts of women, and the udders of other animals, for the nourishment of their young. Its contents are of three kinds: 1st. An oily part, which, whatever may be said concerning the origin of other oils in the body, is certainly immediately derived from the oil of the vegetables taken in, as with these it agrees very exactly in its nature, and would entirely, if we could separate it fully from the coagulable part. Another mark of agreement is their separability, which proves that the mixture has

been lately attempted, but not fully performed. 2dly. Besides this oily, there is a proper coagulable part: And, 3dly. Much water accompanies both, in which there is dissolved a saline saccharine substance. These three can be got separate in cheese, butter, and whey; but never perfectly so, a part of each being always blended with every other part. Milk by evaporation yields a sweet saline matter, of which Dr. Lewis gives the following proportion:

Twelve ounces of	Left of dry matter	From which water extracted a sweet saline substance amounting to—
Cows' milk	13 drachms.	1½ drachms.
Goats' milk	12½	1½
Human milk	8	6
Asses' milk	8	6

The saline substance extracted from asses' milk was white, and sweet as sugar; those of the others brown or yellow, and considerably less sweet: that from cows' milk had the least sweetness of any. On distilling 12 quarts of milk in balneo marie, at least 9 quarts of pure phlegm were obtained; the liquor which afterwards arose was acidulous, and by degrees grew sensibly more and more acid as the distillation was continued. After this came over a little spirit, and at last an empyreumatic oil. The remaining solid matter adhered to the bottom of the retort, in the form of elegant shining black flowers, which being calcined and elixated, yielded a portion of fixed alkaline salt. Milk set in a warm place throws up to the surface an unctuous cream, from which, by agitation, the butter is easily separated. The addition of alkaline salts prevents this separation, not (as some have supposed) by absorbing an acid from the milk, but by virtue of their property of intimately uniting oily bodies with watery liquors. Sugar, another grand intermedium betwixt oils and water, has this effect in a greater degree, though that concrete is by no means alkaline, or an absorbent of acids. The sweet saccharine part of the milk remains dissolved in the whey after the separation of the curd or cheesy matter, and may be collected from it in a white crystalline form, by boiling the whey till all remains of the curdled substance have fallen to the bottom; then filtering, evaporating it to a due consistence, setting it to shoot, and purifying the crystals by solution in water and a second crystallization. Much has been said of the medicinal virtues of this sugar of milk, but it does not seem to have any considerable ones: it is from cows' milk that it has been generally prepared; and the crystals obtained from this kind of milk have but little sweetness. New cows' milk, suffered to stand for some days on the leaves of butterwort or sundew, becomes uniformly thick, slippery, and coherent, and of an agreeable sweet taste, without any separation of its parts. Fresh milk added to this, is thickened in the same manner, and this successively. In some parts of Sweden, as we are informed in the Swedish Memoirs, milk is thus prepared for food.

MILK, in the Wine Trade. The coopers know very well the use of skimmed milk, which makes an innocent and efficacious forcing for the fining down of all white wines, arracks, and small spirits; but it is by no means to be used for red wines, because it discharges their colour. Thus, if a few quarts of well skimmed milk be put into a hoghead of red wine, it will soon precipitate the greater part of the colour, and leave the whole nearly white: and this is of known use in the turning of red wines, when pricked, into white; in which a small degree of acidity is not so much perceived. Milk is, from this quality of discharging colour from wines, of use also to the wine-coopers, for the whitening of wines that have acquired a brown colour from the cask, or from having been hastily boiled before fermenting; for the addition of a little skimmed milk, in these cases, precipitates the brown colour, and leaves the wines almost limpid, or of what they call a water whiteness, which is much coveted abroad in wines as well as in brandies.

MILK of Lime.—MILK of Sulphur. The name of milk is given to substances very different from milk properly so

called, and which resemble milk only in colour. Such is water in which quicklime has been slaked, which acquires a whiteness from the small particles of the lime being suspended in it, and has hence been called the milk of lime. Such also is the solution of liver of sulphur, when an acid is mixed with it, by which white particles of sulphur are made to float in the liquor.

MILK of Vegetables. For the same reason that milk of animals may be considered as a true animal emulsion, the emulsive liquors of vegetables may be called vegetable milks. Accordingly, emulsions made with almonds, are commonly called milk of almonds. But besides this vegetable milk, which is in some measure artificial, many plants and trees contain naturally a large quantity of emulsive or milky juices. Such are lettuce, spurge, fig-tree, and the tree which furnishes the elastic American resin. The milky juices obtained from all these vegetables, derive their whiteness from an oily matter mixed and undissolved in a watery or mucilaginous liquor.

MILK-THISTLE. *Carduus Marianus.*—The young leaves in the spring, cut close to the root with part of the stalks on, are said to be good when boiled.

MILKY WAY. See GALAXY.

MILL, is properly an engine for grinding corn and other substances; but the same term is also used to denote a variety of machines, particularly if the first mover be either wind or water.

Bark MILL, a mill constructed for the purpose of grinding and preparing bark, till it is fit for the use of a tanner. Bark-mills, like most other mills, are worked sometimes by means of horses, at others by water, and at others by wind. One of the best mills we have seen described for these purposes, is that invented by Mr. Bagnall, of Worsley, in Lancashire: this machine will serve not only to chop bark, to grind, to riddle, and pound it; but to beam or work green hides and skins out of the mastering or drench, and make them ready for the ounce or bark liquor; to beam sheepskins and other skins for the skinner's use; and to scour and take off the bloom from tanned leather, when in the currying state. The nature and connexion of its different parts may be understood from the three following figures, Plate II., MECHANICS. Fig. 4, is a horizontal plan of the mill. Fig. 5, longitudinal section of it. Fig. 6, transverse section of it. A, the water-wheel, by which the whole machinery is worked. B, the shafts. C, the pit-wheel, which is fixed on the water-wheel shaft B, and turns the upright shaft E, by the wheel F, and works the cutters and hammer by tapets. D, the spur and bevil-wheel at the top of upright shaft. E, the upright shaft F, the crown-wheel, which works in the pit wheel C. G, the spur-nut to turn the stones I. P, the beam, with knives or cutters fixed at the end, to chop or cut the bark; which bark is to be put upon the cutters or grating i, on which the beam is to fall. Q, the tryal that receives the bark from the cutters i, and conveys it into the hopper H; by which it descends through the shoe J to the stones I, where it is ground. K, the spout, which receives the bark from the stones, and conveys it into the tryal L; which tryal is wired to sift or dress the bark, as it descends from the stones I. M, the trough to receive the bark that passes through the tryal L. R, the hammer, to crush or bruise the bark that falls into the dish S, which said dish is on the incline, so that the hammer keeps forcing it out of the lower side of the said dish, when bruised. A, a trough to receive the dust and moss that passes through the tryal Q. T, the bevil-wheel, that works in the wheel D, which works the beam-knife by a crank V at the end of the shaft u. W, the penetrating rod, which leads from the crank V to the start x. x, the start, which has several holes in it to lengthen or shorten the stroke of the beam-knife. y, the shaft, to which the slide rods a, a, are fixed by the starts n, n. a, the slide rod, on which the knife f is fixed; which knife is to work the hides, &c. On the knife are two springs a, a, to let it have a little play as it makes its stroke backwards and forwards, so that it may not scratch or damage the hides, &c. z, is a catch in the slide-rod a, which catches on the arch-head e; and the said arch-head conveys the knife back without touching the hide, and then falls back to receive the catch again. l, the roller to take up the slide-rod a, while the hides are shifting on the beam b by pulling at the handle m. b, the beam to work the hides, &c. on. Each beam has four wheels p, p, working in a trough

road, *g, g*, and removed by the levers *c, c*. When the knife has worked the hide, &c. sufficiently in one part, the beam is then shifted by the lever *c* as far as is wanted. *d*, a press, at the upper end of the beam, to hold the hide fast on the beam while working. *e*, an arch-head, on which the slide-rod *h* catches. *f*, the knife fixed on the slide-rod *h*, to work the hides, &c. *i*, Cutters or grating to receive the bark for chopping. The beam *P*, with knives or cutters, may either be worked by tapers, as described, or by the bevil-wheel *T*, with a crank, as *V*, to cut the same as shears. The knife *f* is fixed at the bottom of the start, which is fixed on the slide-rod *h*; the bottom of the start is split open to admit the knife, the width of one foot; the knife should have a gudgeon at each end, to fix in the open part of the start; and the two springs *a, a*, prevent the knife from giving too much way when working; the knife should be one foot long and four or five inches broad. The arch-head *e* will shift nearer to, or further from, the beam *h*, and will be fixed so as to carry the knife back as far as is wanted, or it may be taken away till wanted. The roller *l* is taken up by pulling at the handle *m*, which takes up the slide-rod so high as to give head-room under the beam-knife. The handle may be hung upon a hook for that purpose. The slide-rod will keep running upon the roller all the time the hide is shifting; and when the hide is fixed the knife is put on the beam again by letting it down by the handle *m*. There may be two or more knives at work on one beam at the same time, by having different slide-rods. There should be two beams, so that the workmen could be shifting one hide, &c. while the other was working. The beam must be flat, and a little on the slope. As to the breadth, it does not signify; the broader it is the less shifting of the hides will be wanted, as the lever *c* will shift them as far as the width of the hide, if required. Mr. Bagnall has formed a kind of press *d*, to let down, by a lever, to hold the hide fast on each side of the knife if required, so that it will suffer the knife to make its back stroke without pulling the hide up as it comes back. The slide-rod may be weighted, to cause the knife to lay stress on the hide, &c. according to the kind and condition of the goods to be worked. Hides and skins for the skinner's use are worked in the same way as for the tanners. Scouring of tanned leather for the currier's use will be done on the beam, the same as working green hides. It is only taking the knife away, and fixing a stone in the same manner as the knife by the said joint, and to have a brush fixed to go either before or after the stone. The leather will be better secured this way than by band, and much sooner. The whole machinery may be worked by water, wind, steam, or any other power. And that part of the machinery which relates to the beaming part of the hides may be fixed to any horse bark-mill, or may be worked by a horse or other power separately.

Barker's Mill, is a kind of water-mill, invented by Dr. Barker, which without wheel or trundle performs the operation of grinding corn. This mill is represented in fig. 7, Plate II. of *Mechanics*, in which *A* is a pipe or channel that brings water from a reservoir to the upright tube. The water runs down the tube, and thence into the horizontal trunk *C*, which has equal arms; and runs out through holes at *d* and *e*, opening on contrary sides near the ends of those arms. These orifices *d, e*, have sliders fitted to them, so that their magnitude may be increased or diminished at pleasure. The upright spindle *D* is fixed in the bottom of the trunk, and screwed to it below by the nut *g*; and is fixed into the trunk by two cross bars *f*: so that, if the tube *B* and trunk *C* be turned round, the spindle *D* will be turned also. The top of the spindle goes square into the rynd of the upper mill-stone *H*, as in common mills; and as the trunk, tube, and spindle, turn round, the mill-stone is turned round thereby. The lower or quiescent mill-stone is represented by *I*; and *K* is the floor on which it rests, in which is the hole *L* to let the meal run through, and fall down into a trough which may be about *M*. The hoop or case that goes round the mill-stone rests on the floor *K*, and supports the hopper, in the common way. The lower end of the spindle turns in a hole in the bridge-tree *G F*, which supports the mill-stone, tube, spindle, and trunk. This tree is moveable on a pin at *A*, and its other end is supported by an iron rod *N* fixed into it, the top of the rod going through the first bracket *O*, and having a screw-nut *o* upon it, above the

bracket. By turning this nut forward or backward, the mill-stone is raised or lowered at pleasure. Whilst the tube *B* is kept full of water from the pipe *A*, and the water continues to run out from the ends of the trunk; the upper mill-stone *H*, together with the trunk, tube, and spindle, turn round. But if the holes in the trunk were stopped, no motion would ensue, even though the trunk and tube were full of water. For, if there were no hole in the trunk, the pressure of the water would be equal against all parts of its sides within. But when the water has free egress through the holes, its pressure there is entirely removed: and the pressure against the parts of the sides which are opposite to the holes turns the machine.

Mr. James Rumsey, an American gentleman, has rather improved this machine, by conveying the water from the reservoir, not by a pipe as *A D B*, in great part of which the spindle turns, but by a pipe which descends from *A*, without the frame *L N*, till it reaches as low, or lower, than *G*; and then to be conveyed by a curvilinear neck and collar from *G* to *g*, where it enters the arms, as is shewn by the dotted lines at the lower part of the figure. A like improvement was made by M. Segner, a German.

Most of the authors who have attempted to lay down the theory of this mill have fallen into error: the most ingenious theory we have yet seen is by Dr. Gregory, who from a rigid investigation of the *modus operandi*, deduces the following easy practical rules for the construction of this mill:—1. Make each arm of the horizontal tube, from the centre of motion to the centre of the aperture, of any convenient length, not less than $\frac{1}{2}$ of the perpendicular height of the water's surface above these centres. 2. Multiply the length of the arm in feet, by $\cdot 61366$, and take the square root of the product for the proper time of a revolution in seconds; and adapt the other parts of the machinery to this velocity: or, 3. If the time of a revolution be given, multiply the square of this time by $1\cdot 6296$ for the proportional length of the arm in feet. 4. Multiply together the breadth, depth, and velocity, per second, of the race, and divide the last product by $14\cdot 27$ times the square root of the height, for the area of either aperture: or, multiply the continual product of the breadth, depth, and velocity, of the race, by the square root of the height, and by the decimal $\cdot 07$; the last product, divided by the height, will give the area of the aperture. 5. Multiply the area of either aperture by the height of the head of water, and the product by $55\cdot 775$ (or 56 lbs.) for the moving force, estimated at the centres of the apertures in pounds avoirdupois. 6. The power and velocity at the apertures may be easily reduced to any part of the machinery, by obvious rules.

Wind Mill, as its name imports, is a machine or mill that receives motion from the impulse of the wind. Fig. 1, in the plate represents a windmill, whose internal structure is much the same as a water mill, but the external surface consists of the circular building *M N*, that contains the machinery; *E* the extremity of the wind shaft, or chief axis, which is generally inclined from 8 to 15 degrees to the horizon; and *E A, E B, E C, E D*, are four rectangular frames, upon which sails of cloth of the same form are stretched. At the extremity *G* of the sails, their surface is inclined to the axis 72° , and at their furthest extremities *A D*, &c. the inclination of the sail is about 83° . Now when the sails are adjusted to the wind, which happens when the wind blows in the direction of the wind-shaft *E*, the impulse of the wind upon the oblique sails may be resolved into two forces, one of which acts at right angles to the windshaft, and is therefore employed solely in giving a motion of rotation to the sails and the axis upon which they are fixed. When the mill is used for grinding corn, a crown wheel, fixed to the principal axis *E*, gives motion to a lantern or trundle, whose axis carries the moveable mill-stone.

Method of Turning the Sails to the Wind.—That the wind may act with the greatest efficacy upon the sails, the windshaft must have the same direction as the wind. But as this direction is perpetually changing, some apparatus is necessary for bringing the windshaft and sails into their proper position. This is sometimes effected by supporting the machinery on a strong vertical axis, whose pivot moves in a brass socket firmly fixed into the ground, so that the whole machine, by means of a lever may be made to revolve upon this axis, and be properly adjust-

ed to the direction of the wind. Most wind-mills, however, are furnished with a moveable roof, which revolves upon friction rollers inserted in the fixed kerb of the mill; and the adjustment is effected by the assistance of a simple lever. As both these methods of adjustment require the assistance of man, it would be very desirable that the same effect should be produced solely by the action of the wind. This may be done by fixing a large wooden vane or weather-cock at the extremity of a long horizontal arm which lies in the same vertical plane with the windshaft. By this means, when the surface of the vane, and its distance from the centre of motion, are sufficiently great, a very gentle breeze will exert a sufficient force upon the vane to turn the machinery, and will always bring the sails and windshaft to their proper position. This weather-cock, it is evident, may be applied either to machines which have a moveable roof, or which revolve upon a vertical arbor.

On the Form and Position of Wind Mill Sails.—It appears from the investigations of Parent, that a maximum effect will be produced, when the sails are inclined $54\frac{1}{2}$ degrees to the axis of rotation, or when the angle of weather is $35\frac{1}{2}$ degrees.* The angle of inclination assigned by Parent is certainly the most efficacious for giving motion to the sails from a state of rest, and for preventing them from stopping when in motion; but he has not considered that the action of the wind upon a sail at rest is different from its action upon a sail in motion; for since the extremities of the sails move with greater rapidity than the parts nearer the centre, the angle of weather should be greater towards the centre than at the extremity, and should vary with the velocity of each part of the sail. The following table exhibits the angle of inclination and weather which must be given to different parts of the sails.

Parts of the Radius from the centre of motion at E.	Velocity of the sail at these distances, or values of c .	Angle made with the axis.	Angle of Weather.
		Deg. Min.	Deg. Min.
1	$\frac{a}{3}$	63 26	26 34
2	$\frac{2a}{3}$	69 54	20 6
$\frac{1}{2}$ or $\frac{1}{3}$	a	74 19	16 4
$\frac{1}{3}$ or $\frac{1}{4}$	$\frac{4a}{3}$	77 20	12 40
$\frac{1}{4}$	$\frac{5a}{4}$	79 27	10 33
$\frac{1}{5}$	$\frac{2a}{5}$	81 0	9 0

Results of Smanton's Experiments.—Mr. Smanton found from a variety of experiments, that the common practice of inclining plane sails from 72° to 75° to the axis, was much more efficacious than the angle assigned by Parent, the effect being as 45 to 31. When the sails were weathered in the Dutch manner, that is, when their surfaces were concave to the wind, and when the angle of inclination increased towards their extremities, they produced a greater effect than when they were weathered either in the common way, or according to Euler's theorem. But when the sails were enlarged at their extremities as represented at $a\beta$, in fig. 2, so that $a\beta$ was one third of the radius ED, and aD to $D\beta$ as 6 to 3, their power was greatest of all, though the surface acted upon by the wind remained the same. If the sails be farther enlarged, the effect is not increased in proportion to the surface; and besides, when the quantity of cloth is great, the machine is much exposed to injury by sudden squalls of wind. In Mr. Smanton's experiments, the angle of

* The weather of the sails, is the angle which the surface forms with the plane in which they move, and is equal to the complement of the angle which that surface forms with the axis.

weather varied with the distance from the axis; and it appeared from several trials, that the most efficacious angles were those in the following table.

Parts of the Radius EA, which is divided into 6 parts.	Angle with the Axis.	Angle of Weather.
1	72	18
2	71	18
3	72	18 middle
4	74	16
5	77	12
6	83	9

If the radius ED of the sail be 30 feet, then the sail will commence at $\frac{1}{5}$ ED, or 6 feet from the axis, where the angle of inclination will be 72° . At $\frac{1}{3}$ ED, or 10 feet from the axis, the angle will be 71° , and so on.

On the Effect of Wind Mill Sails.—The following maxims, deduced by Mr. Smanton from his experiments, contain the most accurate information upon this subject.

Maxim 1. The velocity of wind-mill sails, whether unloaded or loaded, so as to produce a maximum effect, is nearly as the velocity of the wind, their shape and position being the same. *2.* The load at the maximum is nearly, but somewhat less than as the square of the velocity of the wind, the shape and position of the sails being the same. *3.* The effects of the same sails at a maximum, are nearly, but somewhat less than, as the cubes of the velocity of the wind. *4.* The load of the same sails at the maximum is nearly as the squares, and their effects as the cubes, of their number of turns in a given time. *5.* When sails are loaded, so as to produce a maximum at a given velocity, and the velocity of the wind increases, the load continuing the same; 1st, The increase of effect, when the increase of the velocity of the wind is small, will be nearly as the square of those velocities; 2dly, When the velocity of the wind is double, the effect will be nearly as 16:27; But, 3dly, When the velocities compared are more than double of that where the given load produces a maximum, the effects increase nearly in the simple ratio of the velocity of the wind. *6.* In sails where the figure and positions are similar, and the velocity of the wind the same, the number of turns in a given time will be reciprocally as the radius or length of the sail. *7.* The load at a maximum, that sails of a similar figure and position will overcome at a given distance from the centre of motion, will be as the cube of the radius. *8.* The effects of sails of similar figure and position are as the square of the radius. *9.* The velocity of the extremities of Dutch sails, as well as of the enlarged sails, in all their usual positions when unloaded, or even loaded to a maximum, are considerably quicker than the velocity of the wind.

A new mode of constructing the sails of windmills has been recently given by Mr. Sutton, and fully described by Mr. Hedges, of Barton, in a work exclusively devoted to the subject. Mr. Sutton gives his sails the form represented in fig. 4. and makes the angle of weather at the point M, equidistant from A and B, equal to $22^\circ 30'$. The inclination of the sail at any other point N of the sail, is an angle whose sine is the distance of that point from the centre of motion A, the radius being the breadth of the sail at that point. Fig. 3, shews the angle at the different points of the sail; and the apparent and absolute breadth of the sail at these points. Mr. Sutton's mode of regulating the velocity of the sails, and of bringing them to a state of rest, is particularly ingenious.

We shall now, therefore, proceed to describe a wind-mill, varying in many respects from the common construction. This mill was invented by James Verrier, of North Curry, in Somersetshire, who received a premium from the Society of Arts, for this useful specimen of his ingenuity. Verrier has contrived a register or regulator, by which the vanes are suffered to yield, and give way to the impetus of the wind, when it is too forcible; and when it is too languid, it brings the vanes up to the wind.

till its force is sufficient to give the mill a proper degree of velocity; by this contrivance, the wind is justly proportioned to the resistance or number of stones put to work, and the mill less liable to be set on fire, or destroyed by the violence of its motion. The vertical shaft of this mill is also much shorter than usual, in consequence of which the whole building (and especially the floor on which the stones are placed) is considerably stronger, and less liable to vibrate than in the common mills.

This mill, which has eight quadrant sails, is represented in fig. 5, plate WINDMILLS, where AAA are the three principal posts, 20 feet, 7½ inches long, 20 inches broad at their lower extremities, 10 inches at their upper, and 17 inches thick. The column B is 12 feet 10½ inches long, 19 inches in diameter at its lower extremity, and 26 inches at its upper; it is fixed in the centre of the mill, passes through the first floor E, having its upper end secured by the rails G G. E E E are the girders of the first floor, one of which is only seen, being 8 feet 3 inches long, 11 inches broad, and 9 inches thick; they are mortised into the principal posts A A A and the column B, and are about 6 feet 3 inches above the ground floor. D D D are three posts, 6 feet 4 inches long, 9 inches broad, and 6 inches thick; they are mortised into the girders E F of the first and second floor, 2 feet 4 inches distant from the posts A, &c. F F F are the girders of the second floor, 6 feet long, 11 inches broad, and 9 inches thick; they are mortised into the posts A, &c. and rest upon the upper ends of the posts D, &c. The three rails G G G are 3 feet 1½ inch long, 7 inches broad, and 3 inches thick; they are mortised into the posts D and the upper end of the column B, 4 feet 3 inches above the floor to their upper edges. P is one of the arms which support the extremities of the bray-trees; its length is 2 feet 4 inches, its breadth 8 inches, and its thickness 6 inches. I is one of the bray-trees into which the extremity of one of the bridge-trees K is mortised. Each bray-tree is 4 feet 9 inches long, 9½ inches broad, and seven thick; and each bridge-tree is 4 feet 6 inches long, 9 inches broad, and 7 thick, being curved 9 inches from a right line, and furnished with a piece of brass on its upper surface, to receive the under pivot of the mill-stones. L L are two iron screw bolts which raise or depress the fore-ends of the bray-trees. M M M are the three millstones, and N N N the iron spindles, each 9 feet long, on which the upper mill-stones are fixed. O is one of three wallowers which are fixed in the upper ends of the spindles N N N; they are 16 inches in diameter, and each is furnished with 14 trundles. S is one of the carriage-rails in which the upper pivot of the spindle turns, and is 4 feet 2 inches long, 7 inches broad, and 1 inch thick. It turns on an iron bolt at one end, the other end sliding in a bracket fixed to one of the joists, and forms a mortise in which a wedge is driven to set the rail and wallower in or out of its work: z is the horizontal spur-wheel that gives motion to the wallowers; it is 6 feet 8 inches diameter, is fixed to the perpendicular shaft T, and has 42 cogs or teeth. The perpendicular shaft T is 9 feet 1 inch long, and 14 inches in diameter, having two iron spindles, the under spindle turns in a brass block let flush into the higher end of the column B, and the upper spindle turns in a brass plate inserted into the lower surface of the carriage rail C. The spur-wheel z is fixed on the upper end of the vertical shaft T, and is turned by the crown wheel v on the windshaft e; it is 3 feet 2 inches in diameter, and is furnished with 15 cogs. The carriage rail C, which is fixed on the sliding kerb x, and supports the upper pivot of the vertical shaft, is 17 feet 2 inches long, 1 foot broad, and 9 inches thick. Y Y Q, is the fixed bolt, 17 feet 3 inches diameter, 14 inches broad, and 10 inches thick, mortised into the posts A A A, and fastened with screw bolts. The sliding kerb x is of the same diameter and breadth as the fixed kerb, but its thickness is only 7½ inches. It revolves on 12 friction rollers inserted on the upper surface of the kerb Y Y Q, and has 4 iron half staples Y Y, &c. fastened on its lower edge, the perpendicular arms of which are 10 inches long, 2 inches broad, and 1½ inch thick, and embrace the outer edge of the fixed kerb, to prevent the sliding one from being blown off. The capstalls X, V, of the mill are 18 feet 9 inches long, 11 inches broad, and 1 foot thick; they are fixed at each end with strong iron screw bolts to the sliding kerb, and to the carriage-rail C. On the right hand of x is seen the extremity

of a cross rail, which is fixed into the capstalls X and V by strong iron bolts; e is a bracket 5 feet long, 18 inches in its extreme breadth, and 10 inches thick; it is bushed with a strong brass collar, in which the under spindle of the windshaft turns, and is fixed to the cross rail w, with iron screw bolts and nuts; b is another bracket 7 feet long, 4 feet broad, and 10 inches thick; it is let into the four ends of the capstalls, and that it may embrace the collar of the windshaft, it is divided into two parts, which are fixed together with screw bolts. The windshaft e is 15 feet long, 3 feet in diameter at the fore end, and 18 inches at the back end; its pivot at the back end is 6 inches diameter; and the shaft has a hole bored through it to admit an iron rod to pass easily through. The vertical crown wheel v is six feet in diameter, having 54 cogs which turn the spur wheel r. The bolster d, which is 6 feet 3 inches long, 13 inches broad, and 6 inches thick, is tenoned in the cross rail w, directly under the centre of the windshaft, having a brass pulley fixed in a mortise at its fore end. On the upper surface of this bolster is a groove in which the sliding bolt R moves, having a brass stud at its fore end. This sliding bolt is not distinctly seen in the figure, but the round top of the brass stud is visible below the letter A; the back end of the iron rod that passes through the windshaft bears against the brass stud. The sliding bolt is 4 feet 9 inches long, 9 inches broad, and 4 inches thick. At its fore end is fixed a line which passes over the brass pulley in the bolster, and appears at a with a weight attached to its other end, sufficient to make the sails face the wind that is strong enough to work the number of stones employed; and when the pressure of the wind is more than sufficient, the sails turn on an edge, and press back the sliding bolt, which prevents their going with too great velocity; and whenever the wind abates, the sails by the weight e are pressed up to their proper place again. By this apparatus the wind is regulated, and justly proportioned to the resistance or work at any time to be performed; an uniformity of motion is likewise secured, and the mill is far less likely ever to move with so rapid a motion as to risk its destruction.

That the reader may understand how these effects are produced, we have represented, in fig. 6, the iron rod and the arms which bear against the vanes or sails; a is the iron rod which passes through the windshaft e in fig. 7; A is the extremity which moves in the brass stud that is fixed upon the sliding bolt; ai, ai, &c. are the cross arms at right angles to e A, whose extremities i, i, similarly marked in fig. 7, bear upon the edges of the vanes. The arms ai are 8½ feet long, reckoning from the centre a, 1 foot broad at the centre, and 5 inches thick; the eight arms a, a, &c. that carry the sails are 18½ feet long, their greatest breadth is 1 foot, and their thickness 9 inches, gradually diminishing to their outer ends, where they are only 3 inches in diameter; the inner ends of these arms are mortised into the windshaft. The 4 cardinal sails m, m, m, m, are each 15 feet long, 8 feet broad at their outer ends, and 3 feet at their lower extremities; p, p, &c. are the four assistant sails which have the same dimensions as the cardinal ones, to which they are joined by the line s s s s. The angle of the sail's inclination, when first exposed to the wind, is 45 degrees, and regularly the same from end to end.

It is evident from the preceding description of this machine, that the windshaft e moves along with the sails; the vertical crown wheel v drives the spur wheel r, fixed upon the axis T, which carries also the spur wheel z. This wheel impels the three wallowers O, one of which only is seen in the figure; these being fixed upon the spindles N, &c. communicate motion to the turning mill-stones.

Mr. John Bywater, of Nottingham, took out a patent in September, 1804, for a method of clothing and unclothing the sails of windmills while in motion, (provided they are made after the Dutch manner,) by which the mill may be clothed either in whole or in part, in an easy and expeditious manner, by a few revolutions of the sails, whether they are going fast or slow, leaving the surface smooth, even, and regular in breadth from top to bottom; and in like manner the cloth, or any part of it, may be rolled or folded up to the whip at pleasure, by simple and durable machinery. The invention consists in either folding or unfolding the cloths while the sails are in motion, by means of cylinders or rollers of any shape, as long as the sails,

with a toothed wheel at one end of each, working either directly or indirectly into two wheels without arms, which are hung so as to turn upon a ring of iron fixed to the shaft-head close behind the back stocks, and which may be alternately stopped; so that the wheels at the ends of the cylinders must directly, or by means of a connexion of wheels called carriers or nuts, work into them, by revolving round them through the power of the wind acting on the sails; so that the cylinders must necessarily turn round, and roll up or fold, or unroll or unfold the cloth which is fastened to them, according to the respective wheel, without arms; which is stopped for that purpose. Such is the general contrivance; a detailed account with figures may be seen in the Repertory of Arts, &c. vol. vi. N. S.

On Horizontal Wind Mills.—Various opinions have been entertained respecting the relative advantages of horizontal and vertical wind-mills. Mr. Smeaton, with great justice, gives a decided preference to the latter; but when he asserts that horizontal wind-mills have only $\frac{1}{4}$ or $\frac{1}{10}$ of the power of vertical ones, he certainly forms too low an estimate of their power. Mr. Beatson, on the contrary, who has received a patent for the construction of a new horizontal wind-mill, seems to be prejudiced in their favour, and greatly exaggerates their comparative value. From an impartial investigation, it will probably appear, that the truth lies between these two opposite opinions; but before entering on this discussion, we must first consider the nature and form of horizontal wind-mills.

In fig. 4, C K is the windshaft, which moves upon pivots. Four cross bars, C A, C D, I B, F G, are fixed to this arbour, which carry the frames A P I B, D E F G. The sails A I, E G, are stretched upon these frames, and are carried round the axis C K, by the perpendicular impulse of the wind. Upon the axis C K, a toothed wheel is fixed, which gives motion to the particular machinery that is employed. In the figure only two sails are represented; but there are always other two placed at right angles to these. Now, let the sails be exposed to the wind, and it will be evident that no motion will ensue; for the force of the wind upon the sail A I, is counteracted by an equal and opposite force upon the sail E G. In order, then, that the wind may communicate motion to the machine, the force upon the returning sail E G must either be removed by screening it from the wind, or diminished by making it present a less surface when returning against the wind. The first of these methods is adopted in Tartary, and in some provinces of Spain; but is objected to by Mr. Beatson, from the inconvenience and expense of the machinery and attendance requisite for turning the screens into their proper positions. Notwithstanding this objection, however, Mr. Beatson thinks that this is the best method of diminishing the action of the wind upon the returning sails, for the moveable screen may easily be made to follow the direction of the wind, and assume its proper position, by means of a large wooden weathercock, without the aid either of men or machinery. It is true, indeed, that the resistance of the air in the returning sails is not completely removed; but it is at least as much diminished as it can be by any method hitherto proposed. Besides, when this plan is resorted to, there is no occasion for any moveable flaps and hinges, which must add greatly to the expense of every other method.

The mode of bringing the sails back against the wind, which Mr. Beatson invented, is perhaps the simplest and best of the kind. He makes each sail A I to consist of six or eight flaps or vanes, A P b 1, b 1 c 2, &c. moving upon hinges represented by the dark lines, A P, b 1, c 2, &c. so that the lower side b 1, of the first flap overlaps the hinge or higher side of the second flap, and so on. When the wind, therefore, acts upon the sail A I, each flap will press upon the hinge of the one immediately below it, and the whole surface of the sail will be exposed to its action. But when the sail A I returns against the wind, the flaps will revolve round upon their hinges, and present only their edges to the wind, as is represented at E G, so that the resistance occasioned by the return of the sail must not be diminished, and the motion will be continued by the great superiority of force exerted upon the sails in the position A I. In computing the force of the wind upon the sail A I, and the resistance opposed to it by the edges of the flaps in E G, Mr.

Beatson finds, that when the pressure upon the former is 1872 pounds, the resistance opposed by the latter is only about 36 pounds, or $\frac{1}{52}$ part of the whole force; but he neglects the action of the wind upon the arms C A, &c. and the frames which carry the sails, because they expose the same surface in the position A I, as in the position E G. The omission, however, has a tendency to mislead us in the present case, as we shall now see, for we ought to compare the whole force exerted upon the arms, as well as the sail, with the whole resistance which these arms and the edges of the flaps oppose to the motion of the wind-mill. By inspecting fig. 4, it will appear, that if the force upon the edges of the flaps, which M. Beatson supposed to be 12 in number, amounts to 36 pounds, the force spent upon the bars C D, D G, G F, F E, &c. cannot be less than 60 pounds. Now, since these bars are acted upon with an equal force, when the sails have the position A I, $1872 + 60 = 1932$ will be the force exerted upon the sail A I, and its appendages, while the opposite force upon the bars and edges of the flaps when returning against the wind will be $36 + 60 = 96$ pounds, which is nearly $\frac{1}{20}$ of 1932, instead of $\frac{1}{52}$ as computed by Mr. Beatson. Hence we may see the probable advantages of a screen over moveable flaps, as it will preserve not only the sails, but the arms and the frame which support it, from the action of the wind.

We shall now conclude this article with a comparison of the power of horizontal and vertical wind-mills. Mr. Smeaton rather underrated the former, while he maintained that they have only $\frac{1}{4}$ or $\frac{1}{10}$ the power of the latter. He observes, that when the vanes of a horizontal and vertical mill are of the same dimensions, the power of the latter is four times that of the former, because, in the first case, only one sail is acted upon at once, while in the second case all the four receive the impulse of the wind. This, however, is not strictly true, since the vertical sails are all oblique to the direction of the wind. This calculation proceeds upon a supposition, that the whole force exerted upon vertical sails is employed in turning them round the axis of motion; whereas a considerable part of this force is lost in pressing the pivot of the axis or windshaft against its gudgeon. Mr. Smeaton has overlooked this circumstance, otherwise he could never have maintained that the power of four vertical sails was quadruple the power of one horizontal sail, the dimensions of each being the same. Taking this circumstance into the account, we cannot be far wrong in saying, that in theory at least, if not in practice, the power of a horizontal wind-mill is about $\frac{1}{4}$ or $\frac{1}{3}$ of the power of a vertical one, when the quantity of surface and the form of the sails are the same, and when every part of the horizontal sails has the same distance from the axis of motion as the corresponding parts of the vertical sails. But if the horizontal sails have the position A I, E G, in fig. 4, instead of the position C A d m, C D e n, their power will be greatly increased, though the quantity of surface is the same, because the part C P 3 m being transferred to B I 3 d, has much more power to turn the sails.

Smeaton's Machine for Experiments on Wind Mill Sails.—In the experiments with this machine, the sails were carried round in the circumference of a circle, so that the same effect was produced as if the wind had struck the sails at rest with the velocity which was then given them. In the pyramidal frame, fig. 7, A B C is fixed the axis D E, which carries the arm F G with the sails G I. By pulling the rope Z, which coils round the barrel H, a motion of rotation is given to the sails, so that they revolve in the circumference of a circle, whose radius is D I. At L is fixed a cord which passes round the pulleys M, N, O, and coils round a small cylinder on the axis of the sails, and raises the scale C, in which the different weights are placed for trying the power of the sails, and which being in the direction of the axis D E, is not affected by the circular motion of the arm D G. The scale C is kept steady by the pillars Q, R, and prevented from swinging by the chains S, T, which hang loosely round the pillars. V X is a pendulum composed of two leaden balls moveable upon a wooden rod, so that they can be adjusted to vibrate in any given time. The pendulum hangs upon a cylindrical wire, on which it vibrates as on a rolling axis.

Canicular MILL for Grinding Indigo, &c.: so named because a dog is the first mover. In many parts of Scotland the country dyers use this machine, as exhibited in fig. 8, plate WINDMILLS,

which is a side elevation or profile of the whole machine. A is the walking or camular wheel, about 21 feet diameter, in which the patient dog walks or runs, producing by means of the equalizing action of the fly wheel K, fixed at the extremity of the shaft, an uniform velocity of from 3 to 6 miles per hour. C is a cross-beam, in which, and a corresponding piece in the floor, works the perpendicular shaft D, on which shaft is fixed the lantern B, driven by the wheel *a, a*, set on the inner face of the walking wheel; H, a pinion set on the shaft D; F, a horizontal arm fixed to the shaft D, and in one extremity of which, and the opposite point in the upper cover of the lantern B, the box G is set on pivots; L, an iron vessel, placed within the box, and containing the materials to be pulverized, together with three 18 lb. iron shots; I is a wheel under the bottom of the box G, driven by the pinion H. The action of the machine will now be readily understood. E is driven by the action of the first mover; H, set on the same shaft will drive I, giving G and the vessel L a horizontal motion on its pivots, while E carries it horizontally about the shaft D; the compound motion then produced will effect the operation of grinding, by the centrifugal motion of the balls.

Fig. 9 is a portion of the wheel A, seen in profile, or in front elevation, and having one of its sides taken off to exhibit the action of the dog at B; C is an aperture in any part of one side, for the ingress and egress of the animal; D shows the situations of the balls when the machine is in action; B is inserted to afford the opportunity of explaining, that the figure of the vessel L must be varied with the required rate of motion. If the velocity be reduced, either by the circumstances of the material, or the incapacity of the animal, the vessel must assume a flatter figure, as E; if the velocity be increased, the vessel must be deeper, in proportion to its width.

Rustall's Family Mill cannot but be highly useful in the country, and we shall here describe the *Family Mill and Bolter* of Mr. Rustall, of Purbrook-heath, near Portsmouth, for which he received a premium of 40 guineas from the Society of Arts.

In plate MANULE, see fig. 10, A is the handle of the mill; B one of the millstones, which is about 30 in. in diameter, and 5 in. in thickness, moving with its axis C; D is the other millstone, which, when in use, is stationary, but which may be placed near to, or at a distance from, the moveable stone B, by means of three screws passing through the wooden block E, that supports one end of the axis C; after it has been put through a hole or perforation in the bed stone. The grain likewise passes through this perforation from the hopper F, into the mill. F represents the hopper, which is agitated by two iron pins on the axis C, that alternately raise the vessel containing the grain, which again sinks by its own weight. In consequence of this motion, the corn is conveyed through a spout that passes from such hopper into the centre of the mill behind, and through the bedstone D. G, a paddle regulating the quantity of corn to be delivered to the mill; and, by raising or lowering which, a larger or smaller proportion of grain may be furnished; H, the receptacle for the flour, into which it falls from the millstones, when ground; I represents one of the two wooden supporters on which the bedstone D rests. These are screwed to the block E, and likewise mortised into the lower framework of the mill at K, which is connected by means of the pins or wedges L, L, L, that admit the whole mill to be easily taken to pieces; M, a fly wheel, placed at the furthest extremity of the axis C, and on which another handle may be occasionally fixed; N, a small rail, serving to keep the hopper in its place; the furthest part of such hopper resting on a small pin, which admits of sufficient motion for that vessel to shake forward the corn; O, a spur rail, for strengthening the framework of the mill; P, the front upright that is mortised into the framework, and serves as a rest for the end of the iron axis C, which is next to the handle. Lastly, there is a cloth laid fixed to a broad wooden hoop, which is placed over the stones while working, to prevent the finer particles of flour from escaping.

The bolter is here represented with its front removed, in order to display its interior structure; the machine being 3 feet 10 inches in length, 19½ inches in breadth, and 18 inches in depth. A is a moveable partition, sliding about 4 feet backwards or forwards, from the centre of the box, upon two

wooden ribs, which are fixed to the back and front of the box, and one of which is delineated at the letter B; C, the lid of the bolter, represented open; D, a slider, which is moveable in a groove made in the lid, by means of two handles on the back

of such lid; E, a forked iron fixed in the slider D, and which, when the lid is shut, takes hold of the edge of the sieve F, and moves it backwards and forwards on the wooden ribs B, according to the agitation of the slider; G represents a fixed partition in the lower centre of the box, which it divides into two parts, in order to separate the fine from the coarse flour; from this partition the slider A moves each way about four inches, and thus affords room for working the sieve; H, a board that is parallel to the bottom of the bolter, and forms part of the slider A; this board serves to prevent any of the sifted matter from falling into the other partition; I represents two of the back feet, which support the bolter.

Fig. 11 of the plate above mentioned, is a view of the top, or upper part, of the lid of the bolter; K, the slider that moves the lengthwise of the bolter; L, L, the handles by which the slider is worked; M, a screw serving to hold the fork, which imparts motion to the sieve.

Q represents the forked iron E separately from the lid. Both the mill and bolter may be constructed at a moderate expense. The former may be worked even in a public kitchen, or within a room in a farm house, without occasioning any great incumbrance. The particular excellence of the mill consists in this circumstance, that, from the vertical position of its stones, it may be put in action without the intervention of cogs or wheels. It may be adapted to the grinding of malt, the bruising of oats for horses, and for making flour, or for all these purposes. Another advantage peculiar to Mr. Rustall's contrivance is, that one man is sufficient to work it; though a man and a boy will be able to produce, in two hours, a quantity of flour sufficient to serve a family of six or eight persons, for a whole week;—repeated trials have proved, that the mill grinds the corn completely, and at the rate of one bushel of wheat within the hour.

Improved Gunpowder Mill, for lessening the destructive effects of Explosion, by Mr. Monk, manager of the gunpowder mills of Messrs. Burton, near Tunbridge, a model and description of which were presented to the Society of Arts in 1819, who voted the inventor its silver medal, and 20 guineas.

In plate MANULE, fig. 12, *a a* is a compound lever formed of two iron bars, the extremities of which terminate above the bedstones of the pair of mills A B; these levers are connected at their other extremities by a bolt at *b*, forming a joint, and permitting the levers to move so as to form a very obtuse angle, when a power from below upwards is applied to either of the ends of the levers *a a*, as shown by the dotted lines. *c c*, are two oblong holes in the lever bars, through which two screws are put, which being screwed into the two uprights, constitute the two fixed fulcrums of the lever. *d d*, are two uprights, with

an eye or loop in each, to receive and steady the ends of the lever, which are made long enough to allow the bars to take the position indicated by the dotted lines. *ee*, are two blowers made of thin sheet iron, in the form of hollow three-sided pyramids, and are suspended by two iron rods to the ends of the levers *ea*. These blowers are placed as near as possible to the tops of the upright stone shafts, and as close to the wheels as the timber will allow. *ff*, are two copper chains, attached by one end to the lever bars, and by the other supporting two copper valves which are not seen in fig. 1, being inside the tubs, but one of them is shown at *g*, in the section of a tub, fig. 2. *hh*, are two oval tubs capable of holding about six gallons of water, having a circular hole at the bottom. Surrounding this hole is a grooved block having a channel all round it, into which the bottom edges of the cylindrical valves fit, shown in section at fig. 2. *ii*, are two small spring catches fastened to the two uprights. The lever bars are laid on the top of these catches, so that when the ends of the lever rise, that part of the lever which is on the catch moves downward, as shown by the dotted lines, till it slips over the end of the catch; and thus the lever is prevented from resuming its horizontal position, till released from the catch.

In order to fit that part of the apparatus above described for action, bring the lever to a horizontal position, place the valve *g* in the circular channel at the bottom of the tub so as to cover the hole; fill the channel with mercury, and then fill the tub with water. Hence it is evident, that the water is prevented by the mercury from escaping out of the tub, so long as the valve remains in its place. Now, if an explosion happen in either of the mills, the blower *e* hanging over the bedstone, will be thrown up, and the lever will in consequence be brought into the position indicated by the dotted line, and will be retained there by the spring catches *i*; at the same time the valves *g* will be drawn up out of the mercury, and the water in both the tubs will pour down on their respective bedstones, extinguishing in one the inflamed powder, and in the other preventing it from taking fire. In a certain stage of the grinding the materials of the powder are apt to clot, and adhere to the runners; parts of the bedstones are thus left bare, and the runner and bedstone coming in contact, an accidental spark may be elicited, and an explosion ensue. To prevent this most usual cause of accidents, Mr. Monk fixes to the axle of the wheel a scraper, formed of a curved piece of wood *k*, shod with copper, which being placed behind, and almost touching each of the runners, scrapes off the powder as it collects, and thus keeps the bedstone always covered.

l, is the great water wheel which gives motion to the rest. *mm*, are two vertical bevil wheels fixed on the axis of the great wheel. *nn*, two horizontal bevil wheels working in *mm*, and turning the vertical shafts, upon the upper part of which are also fixed two horizontal wheels *oo*, which drive the wheels *pp*. To the shafts of these latter wheels are fixed the runners *qq*, which traverse on the bedstones *uu*. *v, v*, are the curbs surrounding the bedstone, to prevent the powder from falling off.

The Mill A presents a view, and the mill B a section of the bedstone and curb.

Fig. 2 shows the position of the apparatus after an explosion has taken place, the valve being raised up out of the channel, and the water pouring down on the bedstone.

It appears by several certificates, that since these improved mills have been constructed by Mr. Monk, occasional explosions have taken place, which before generally took place under both pair of stones; but since that time, by the effect of instantaneously wetting the powder under the contrary pair of stones, to those where explosion had taken place, a double disaster has been prevented; and in the short space of three years, in a single manufacturing establishment, eight mills have been saved from destruction, and probably many lives.

Pasley's Proposal for increasing the Strength of Gunpowder.—In the annexed figure A D is a longitudinal section of a great gun; C the cartridge; B the ball; E a hollow metal sphere, similar to a bomb-shell or hand-grenade, with a hollow neck or tube G, which screws into the breech of the gun; F the touch-hole. The design is, that the ignited powder in the shell shall throw a quantity of flame suddenly into the gun, and explode every grain of the cartridge powder. It is not, however, meant that

preventing any of the powder from being blown out unignited, is to give the additional force; on the contrary, it is certain that the expansive power of explosive mixtures is as the quantity of flame suddenly formed by them, particularly in confined situations, where the flame is supplied with matter from the combustible substance itself only. In proof of this, let flame be communicated to the powder of a charged gun, by firing a pistol containing powder only in its touch-hole, and the result will be found to be, that the momentum of the ball from the gun will be much greater than if the same quantity of powder as that fired from the pistol had been added to the cartridge in the gun, and the whole exploded in the customary manner. This was ascertained by experiment nearly ten years since. The thing is now put beyond all manner of doubt, from the discharge of guns being effected by detonating copper caps. Sportsmen using the same declare, that a less quantity of powder produces an equal effect to a greater quantity without these caps. It may be necessary to add, that trials are indispensable to ascertain the maximum of the size of the shell *h*, and of the quantity of powder it should contain to be safe and most efficient.—*Query.* Might not the guns of forts be constructed so as to slide backwards and forwards on fixed but centered carriages, by which much fatigue would be avoided by the men? See *GUNPOWDER*.

MILLS, Horse and Hand. These machines derive their action from animal force. In horse-mills, one, two, or more horses, or other cattle, are made either to draw, or push before them levers, which project from a centre shaft bearing the great horizontal wheel that gives motion to the more remote parts, and which act with more or less effect, according to the length of the levers and the number of cattle employed.

MILLS, Oil, are very simple in their construction; they being nearly the same as cider-mills; consisting of troughs wherein the seed is broken by the passage of immense cylinders, or cones, of iron or stone, and afterwards put into presses for the purpose of forcing the oil from the residuum. See *OIL MILL*.

MILLS, Copper and Brass, are almost invariably worked by water, having large wheels that give immediate action to hammers of great weight; these beat out the large slabs and bricks of metal into various forms, such as kettles, coppers, boilers, &c. and roll out sheets for various purposes, but especially for coppering the bottoms of ships. This process is effected by passing the heated metal between two cast-iron cylinders, of about a foot diameter, which having contrary motions, draw it through a small interval left between them; and by reducing the thickness, give greater surface to the sheet.

MILLS, Silk, Cotton, &c. require much delicacy in their construction; their principal movements depend on the same principles as those of the mills described: the more minute parts, such as the bobbins, &c. being moved by means of one or more leather straps passing them in close contact, so as to occasion them to revolve with an astonishing degree of velocity. See *SPINNING*.

MILLS, Saw, though extremely simple in their parts, require the greatest care in their formation. The saws, which are moved by cranks, must be set with most scrupulous exactness. In most instances the timber is brought forward to the saw by means of a small toothed wheel, and an axle whereon the rope that pulls the timber is gradually coiled. See *SAW*.

MILLS, Flax, are generally worked by cattle; their construction is simple; the essential parts being the handle, which combs the flax; and the scutcher, which strikes it: both tend to clearing away the coarser and unequal fibres, and to prepare the material for being spun either by hand or by means of machinery. See *FLAX* and *HAMP*.

MILLENNARIANS, or Chilians, a name given to those who, in the primitive ages, believed that the saints will one day reign on earth with Jesus Christ a thousand years.

MILLION, in Numeration, is one thousand thousands, or 1,000,000. See NUMERATION.

MILLREE, a Portuguese gold coin, value 5s. 7½d. English.

MILT, in Anatomy, a popular name for the spleen.

MILT, or *Melt*, in Natural History, the soft roe in fishes; thus called from its yielding, by expression, a whitish juice resembling milk. See ROE. The milt is properly the seed or spermatic part of the male fish. The milt of a carp is reckoned a choice bit. It consists of two long whitish irregular bodies, each included in a very thin fine membrane. M. Petit considered them as the testicles of the fish wherein the seed is preserved; the lower part next the anus, he supposes to be the vesicula seminales.

MIMOSA, the *Sensitive Plant*, a genus of the polygamia order, in the monœcia class of plants, and in the natural method ranking under the 33d order *Tomentaceæ*. The name *mimosa*, signifies "mimic;" and is given to this genus on account of the sensibility of the leaves, which, by their motion, mimic or imitate the motion of animals. This genus comprises 85 different species, all natives of warm climates. The sensitive kinds are exceedingly curious plants, in the very singular circumstance of their leaves receding rapidly from the touch, and running up close together; and in some sorts, even the foot-stalks are affected, so as instantly to fall downwards as if held by hinges, which last are called *humble sensitives*. They have all winged leaves, each wing consisting of many small pinnæ.

"Naturalists," says Dr. Darwin, "have not explained the immediate cause of the collapsing of the sensitive plant; the leaves meet and close in the night during the sleep of the plant, or when exposed to much cold in the day-time, in the same manner as when they are affected by external violence, folding their upper surfaces together, and in part over each other like scales or tiles, so as to expose as little of the upper surface as may be to the air; but do not, indeed, collapse quite so far, for when touched in the night during their sleep, they fall still further; especially when touched on the foot-stalks between the stems and the leaflets, which seems to be their most sensitive or irritable part. Now, as their situation after being exposed to external violence resembles their sleep, but with a greater degree of collapse, may it not be owing to a numbness or paralysis consequent to too violent irritation, like the faintings of animals from pain or fatigue? A sensitive plant being kept in a dark room till some hours after day-break, its leaves and leaf-stalks were collapsed as in its most profound sleep, and on exposing it to the light, above twenty minutes passed before the plant was thoroughly awake, and had quite expanded itself. During the night the upper surfaces of the leaves are oppressed; this would seem to show that the office of this surface of the leaf was to expose the fluids of the plant to the light as well as to the air." The common sensitive *humble plant* rises with an under shrubby prickly stem, branching six or eight foot high, armed with crooked spines; conjugated, pinnated leaves, with bifurcated partial lobes or wings, having the inner ones the least, each leaf on a long foot-stalk; and at the sides and ends of the branches many purple flowers in roundish heads; succeeded by broad, flat, jointed pods, in radiated clusters. This is somewhat of the *humble sensitive* kind: the leaves, foot-stalks and all, receding from the touch, though not with such facility as in some of the following sorts. The bashful *humble plant* rises with an under shrubby, prickly stem, branching two or three feet round, armed with hairy spines: by the least touch the leaves instantly recede, contract, close, and, together with the foot-stalk, quickly decline downward, as if shamed at the approach of the hand. *M. scandens*, *cacoon*, or *umbellata* with, is frequent in all the upland valleys and woodlands on the north side of Jamaica. It climbs up the tallest trees, and spreads itself in every direction, by means of cirri, or claspers, so as to form a complete arbour, and to cover the space of an English acre from one root. The pod is perhaps the largest and longest in the world; being sometimes eight or nine feet in length, five inches broad, jointed, and containing ten or fifteen seeds. *M. catechu*, according to M. Ker, rises only twelve feet in height, and to one foot in diameter. From this tree, which grows plentifully on the mountainous parts of Indostan, where it flowers in June, is produced the official drug long known in Europe by the name of *terra japonica*.

amica. The true Egyptian *acacia* rises to a greater height than the preceding. The fruit is a long pod resembling that of the lupin, and contains many flattish brown seeds. It is a native of Arabia and Egypt, and flowers in July. Although the *mimosa nilotica* grows in great abundance over the vast extent of Africa, yet gum arabic is produced chiefly by those trees which are situated near the equatorial regions; and we are told that in Lower Egypt the solar heat is never sufficiently intense for this purpose. The gum exudes in a liquid state from the bark of the trunk and branches of the tree, in a similar manner to the gum which is often produced upon the cherry trees, &c. in this country; and by exposure to the air it soon acquires softness and hardness.

MINA, in Grecian Antiquity, a money of account, equal to a hundred drachms.

MINE, in Natural History, a place under ground, where metals, minerals, or even precious stones, are dug up. As, therefore, the matter dug out of mines is various, the mines themselves acquire various denominations, as gold mines, silver mines, copper mines, iron-mines, diamond mines, salt mines, mines of antimony, of alum, &c. Mines, then, in general, are veins or cavities within the earth, whose sides receding from, or approaching nearer to, each other, make them of unequal breadths in different places, sometimes forming larger spaces which are called *boles*, they are filled with substances, which, whether metallic or of any other nature, are called the *lodes*; when the substances forming those lodes are reducible to metal, the lodes are by the miners said to be *alive*; otherwise they are called *dead lodes*. In Cornwall and Devon, the lodes generally hold their course from eastward to westward; though in other parts of England they frequently run from north to south. The sides of the lode never bear in a perpendicular, but constantly under-ly, either to the north or to the south. The lode is frequently intercepted by the crossing of a vein of earth, or stone, or some different metallic substance, in which case it generally happens that one part of the lode is moved a considerable distance to one side. This transient lode is by the miners called *flouking*; and the part of the lode which is to be moved is said to be *heaved*. According to Dr. Nichol's observations upon mines, they seem to be, or to have been, the channels through which the waters pass within the earth, and, like rivers, have their small branches opening into them in all directions. Most mines have streams of water running through them; and when they are found dry, it seems to be owing to the waters having changed their course, as being obliged to it, either because the load has stopped up the ancient passages, or that some new and more easy ones are made. Many mines have been discovered by accident; a torrent first laid open a rich vein of the silver mine at *Friburg* in Germany; sometimes a violent wind, by blowing up trees, or overturning the parts of rocks, has discovered a mine; the same has happened by violent showers, earthquakes, thunder, the firing of woods, or even the stroke of a ploughshare or horse's hoof. The principal signs of a latent metallic vein seem reducible to general heads, such as, 1. The discovery of certain mineral waters. 2. The discoloration of the trees or grass of a place. 3. The finding of pieces of ore on the surface of the ground. 4. The rise of warm exhalations. 5. The finding of metallic sands, and the like. All which are so many encouragements for making a stricter search near the places where any thing of this kind appears; whence rules of practice might be formed for reducing this art to a greater certainty. But when no evident mark of a mine appears, the skillful mineralogist usually bores into the earth, in such places as from some analogy of knowledge gained by experience, or by observing the situation, course, or nature of other mines, he judges may contain metal. After the mine is found, the next thing to be considered is whether it may be dug to advantage. In order to determine this, we are only to weigh the nature of the place, and its situation as to wood, water, carriage, healthiness, and the like, and compare the result with the richness of the ore, and the charge of digging, stamping, washing, and smelting. Particularly, the form and situation of the spot should be well considered. A mine must either happen, 1. In a mountain. 2. In a hill. 3. In a valley. Or 4. In a flat. But mountains and hills are dug with much greater ease and convenience, chiefly because the drains

and burrows, that is, the adits or avenues, may be here readily cut out, both to drain the water, and to form gangways for bringing out the ore, &c. In all the four cases, we are to look out for the veins, which the rains or other accidental thing may have laid bare; and if such a vein be found, it may often be proper to open the mine at that place, especially if the vein prove tolerably large and rich; otherwise the most commodious place for situation is to be chosen for the purpose, *viz.* neither on a flat, nor on the tops of mountains, but on the sides. The best situation for a mine, is a mountainous, woody, wholesome spot, of a fine easy ascent, and bordering on a navigable river.

MINE, in the Military art, denotes a subterranean canal or passage, dug under the wall or ramparts of a fortification, intended to be blown up by gunpowder. The alley or passage of a mine is commonly about four feet square; at the end of this is the chamber of the mine, which is a cavity of about five feet in width and in length, and about six feet in height; and here the gunpowder is stowed. The saucisse of the mine is the train, for which there is always a little aperture left. Two ounces of powder have been found, by experience, capable of raising two cubic feet of earth; consequently, 200 ounces, that is, 12 pounds 8 ounces, will raise 200 cubic feet, which is only 16 feet short of a cubic toise, because 200 ounces, joined together, have proportionally a greater force than two ounces, as being an united force. All the turnings a miner uses to carry on his mines, and through which he conducts the saucisse, should be well filled with earth and dung; and the masonry in proportion to the earth to be blown up, as 3 to 2. The entrance of the chamber of the mine ought to be firmly shut with thick planks, in the form of a St. Andrew's cross, so that the enclosure be secure, and the void spaces shut up with dung or tempered earth. If a gallery be made below or on the side of the chamber, it must absolutely be filled up with the strongest masonry, half as long again as the height of the earth; for this gallery will not only burst, but likewise obstruct the effect of the mine. The powder should always be kept in sacks, which are opened when the mine is charged, and some of the powder strewed about: the greater the quantity of earth to be raised is, the greater is the effect of the mine, supposing it to have the due proportion of powder. Powder has the same effect upon masonry as upon earth, that is, it will proportionally raise either with the same velocity. The branches which are carried into the solidity of walls do not exceed three feet in depth, and two feet six inches in width nearly: this sort of mine is most excellent to blow up the strongest walls. If, when the mines are made, water be found at the bottom of the chamber, planks are laid there, on which the powder is placed either in sacks or barrels of 100 lb. each. The saucisse must have a clear passage to the powder, and be laid in an anget, or wooden trough, through all the branches. When the powder is placed in the chamber, the planks are laid to cover it, and others again across these, then one is placed over the top of the chamber, which is shaped for that purpose; between that and those which cover the powder, props are placed, which shore it up; some inclining towards the outside, others to the inside of the wall; all the void spaces being filled with earth, dung, brick, and rough stones. Afterwards planks are placed at the entrance of the chamber, with one across the top, whereon they buttress three strong props, whose other ends are likewise propped against another plank situated on the side of the earth in the branch; which props being well fixed between the planks with wedges, the branch should then be filled up to its entrance with the forementioned materials. The saucisses which pass through the side branches must be exactly the same length with that in the middle, to which they join: the part which reaches beyond the entrance of the mine is that which conveys the fire to the other three; the saucisses being of equal length, will spring together. From a great number of experiments, it appears, 1. That the force of a mine is always towards the weakest side; so that the disposition of the chamber of a mine does not at all contribute to determine this effect. 2. That the quantity of powder must be greater or less, in proportion to the greater or less weight of the bodies to be raised, and to their greater or less cohesion; so that you are to allow for each cubic fathom of loose earth, 9 or 10 lb.: firm earth and strong sand, 11 or 12 lb.; flat clayey earth, 15 or 16 lb.; new

masonry, not strongly bound, 15 or 20 lb.; old masonry, well bound, 25 or 30 lb. 3. That the aperture, entonnoir, of a mine, if rightly charged, is a cone, the diameter of whose base is double the height, taken from the centre of the mine. 4. That when the mine has been overcharged, its entonnoir is nearly cylindrical, the diameter of the upper extreme not much exceeding that of the chamber. 5. That besides the shock of the powder against the bodies it takes up, it likewise crushes all the earth that borders upon it, both underneath and sideways. To charge a mine so as to have the most advantageous effect, the weight of the matter to be carried must be known; that is, the solidity of a right cone, whose base is double the height of the earth over the centre of the mine: thus, having found the solidity of the cone in cubic fathoms, multiply the number of fathoms by the number of pounds of powder necessary for raising the matter it contains; and if the cone contains matters of different weights, take a mean weight between them all, always having a regard to their degrees of cohesion. As to the disposition of mines, there is but one general rule, which is, that the side towards which one would determine the effect to be the weakest; but this varies according to occasions and circumstances. The calculation of mines is generally built upon this hypothesis, that the entonnoir of a mine is the frustum of an inverted cone, whose altitude is equal to the radius of the excavation of the mine, and the diameter of the whole lesser base is equal to the line of least resistance; and though these suppositions are not quite exact, yet the calculations of mines deduced from them, have proved successful in practice; for which reason this calculation should be followed, till a better and more simple be discovered. M. de Valliere found that the entonnoir of a mine was a paraboloid, which is a solid generated by the rotation of a semiparabola about its axis; but as the difference between these two is very insignificant in practice, that of the frustum of a cone may be used.

Coal MINE. A subterranean excavation, from which coal is dug. The most extensive coal mines in this island are in the north of England and in Scotland. The descent to the Whitehaven mines is through spacious galleries hewn out of the rock; all the coal being cut away except large pillars, which, in deep parts of the mine, are three yards high, and about twelve yards square at the base; such great strength being there required to support the ponderous roof. These are the deepest coal mines that have been hitherto wrought; and, perhaps, no other miners have penetrated to so great a depth below the sea as those of Whitehaven; the very deep mines in Hungary, Peru, and elsewhere, being situated in mountainous regions, where the surface of the earth is elevated to a great height above the level of the ocean. There are here three strata of coal, which lie each at a considerable distance above the other, and there is a communication by pits between one of these parallel strata and another. But the vein of coal is not always regularly continued in the same inclined plane, but instead thereof, the miners meet with hard rock, which interrupts their further progress. At such places there seem to have been breaks in the earth, from the surface downwards; and in some of them it may have sunk ten or twenty fathoms, or even more. These breaks the miners call *dykes*; and when they meet with one of them, their first care is to discover whether the strata in the part adjoining be higher or lower than in the part where they have been working; or, to use their own terms, whether the coal be cast down or up. If it be cast down, they sink a pit to it; but if it be cast up to any considerable height, they are oftentimes obliged, with great labour and expense, to carry a level and long gallery through the rock, until they again arrive at the strata of coal. Those who have the direction of these deep and extensive works are obliged, with great art and care, to keep them continually ventilated with perpetual currents of fresh air. In the deserted works, which are not ventilated with perpetual currents of fresh air, large quantities of damps and noxious exhalations are frequently collected; and in such works they often remain for a long time, without doing any mischief. But when by some accident they are ignited, that is to say, set on fire, they then produce dreadful explosions, and, bursting out of the pits with great impetuosity, like the fiery eruption from burning mountains, they force along with them ponderous bodies to a great height in the air. The

coal in these mines has several times been ignited by these fulminating damp, and has continued burning for many months, until large streams of water were conducted into the mines, and suffered to fill those parts where the coal was burning. By such fires several collieries have been totally destroyed, of which there are instances near Newcastle, and in other parts of England, as well as in Fifeshire.

Professor Jameson, in his recent geological work, has scientifically described the different varieties of coal by several species and numerous sub-species; we shall here give such a description of them in regard to their practical uses, as divided into three kinds, according to their degree of inflammability. The least inflammable are Welsh Coal, Irish, and Kilkeny coal; and blind, or deaf coal, found in many parts of England, Scotland, America, and elsewhere. The last mentioned coal requires a considerable degree of heat to ignite it; but, when once kindled, its combustion lasts a long time: it remains in distinct pieces in the fire without caking, producing neither flame nor smoke, making no cinder, but leaving a stony slag; it makes a hot, glowing fire, like coals or cinders, emitting a suffocating effluvia which renders it unfit for burning in dwelling houses, &c. We think it might be used very advantageously in distilleries; as the ebullition of the liquid might be more easily regulated than with the flaming coal—a circumstance of the utmost importance to the quality of the spirit when distilled by naked fire.

Open burning coal soon kindles, making a hot, pleasant fire, but is soon consumed, and producing both flame and smoke in abundance; it lies open in the fire, and does not cake together to form cinders, its surface being burnt to ashes before it is thoroughly calcined in the middle, leaving only a white ash. Of this kind is cannel coal, jet, peacock, splint, and most of the coals in the Staffordshire coal district and in Scotland.

Close burning coal kindles quickly, makes a very hot fire, melts, and runs together like bitumen;—it makes a more durable fire than any other coal, and burns finally to ashes of a brownish colour. Of this kind are the Newcastle coal and many others. The open burning and the close burning coal, mixed together, make a more profitable fire for domestic uses than either of them separately. The various kinds of coal are often found mixed with each other under ground; and some of the finer sorts run, like veins, between those of a coarser. This natural admixture is often laid, erroneously, to the charge of the coal merchant, by persons unacquainted with the circumstance.

In the plate, fig. 1 represents a section of the Bradley mine, near Bilston in Staffordshire, exhibiting at the same time the various operations of the miners. A, the whimsey or steam engine, for raising the coal from the bottom of the shaft. B, The harkman. C, one of the shafts of the mine. D, a passage from one shaft to the other. E, the gateway, which is the first work of the miners after the shaft is sunk; it is made from eight to ten feet in height, nine feet wide, and is carried to the whole extent of the work. F, the bolt hole made to cause a free circulation of air through the mine, should any part of which take fire, the bolt hole is built up.

G, pillars left in working the ten yard coal, to support the superjacent strata. H, an excavation, called by colliers a stall, who, after the gateway is made, begin thus to work the coal, or hole under. I, the rib through which the air-way is cut. J, the lights. K, a man who hangs on the skips and rakes the gateway. L, M, N, miners, heading, holing, and shovelling out the slack or small coal. O, slack carrier. P, a miner working on a scaffold. Q, the spurn, a small piece of coal left as a support to many tons above, which fall when this is taken away. R, a collier on a scaffold, taking out the spurn as far as he can reach with a pick. S, a collier standing upon a heap of slack, called the gob, with a prong used for that work, which cannot with safety be done with a pick. T, a collier breaking or turning out coal. U, a collier loading a skip. V, a collier breaking the large coal with a wedge. W, a driver with an empty skip. X, a driver with a loaded skip. Y, a skip being drawn up the shaft by the engine. Z, a pillar called the *man of war*, which is left to support the upper strata until the lower are worked; it is then taken away and the upper coal falls down.

The rope or chain by which the loaded skip Y is drawn up, passes round a wheel worked by the steam-engine, and returns to the other shaft of the mine (not shewn in our engraving) where it lets down an empty skip, which is immediately released on its arrival at the bottom, and a loaded skip hooked on, to be drawn up as the one shewn descended when empty. It is an astonishing and highly amusing sight to a stranger, in the neighbourhood of Birmingham, and in other coal and iron districts, to behold at a single coup d'oeil, a vast number of steam engines, with all their massive machinery and apparatus, simultaneously at work in the open air; some employed in drawing up the iron ore, others coals; which, as they emerge from the earth, are sometimes lifted upon an elevated rail road, from whence, by their own gravity or by the aid of machinery, they are at once conveyed with the rapidity of lightning, and thundering in their progress to their destination the contents instantly discharged, and the emptied skip brought back (by the advance of another that is loaded) to the mouth of the shaft, again to descend into the bowels of the earth to be re-loaded, in endless succession. The effect of this scene at night is beyond our feeble power of description, it is in every respect a moving scene; the numerous coke works just give sufficient light to see indistinctly all that is going forward, while the frequent flashing of a more intense light from other sources give a playfulness to the shadows, which picture to the mind a vast multiplication of objects.

The different strata that are cut through to arrive at the principal bed of coal, are exhibited on the left of the shaft, by variously shaded portions of the solid earth, which in Bradley mine are as follow:—

In other mines (and probably in this at a greater depth) a single stratum will sometimes occur, of from 100 to 200 feet in thickness, with very little difference throughout the whole mass. The strata is represented in Bradley mine as nearly horizontal, but this is seldom the case, the strata lying generally in an inclined position to the horizon, which is called by the miners the dip. In consequence of this dip or descent, most of our mines have been commenced working near to the surface of the earth, and as the coal has been cleared away, the mining progressively goes on deeper and deeper. At Newcastle many of the mines extend to a considerable distance. At Whitehaven the coal works are extended more than a mile under the sea, and at between 600 and 700 feet below its bottom; and it has been observed generally, that the coals

at the greatest distance under the sea are the best in quality,—hence the distinguishing term sea coal.

Plan of the Workings of a Coal Mine, near Newcastle-upon-Tyne.—The extensive collieries in the vicinity of Newcastle are preserved from the disastrous consequences which attend the accumulation of the fire-damp, or hydrogen gas, by a complicated and expensive system of ventilation. The following sketch represents, on a small scale, the plan which is pursued to counteract the effects of that fatal evil, and to spread throughout the workings a sufficient quantity of fresh air. The coal is worked in narrow passages called boards and headways; and the dark parts in the plan represent the pillars of coal left to support the roof. There are, generally, two descents to the mine, or more, which are distinguished by the

terms of the upcast or downcast shafts. A, is the downcast shaft by which the air descends, and which is usually assisted by another shaft connected with it; the current of air is represented by the waved line, which is carried through the main passages only, the sub-ways which diverge from them being stopped up by brattices, as *a* and *b*, and its motion is accelerated by the heat of a large furnace situated at the bottom of the upcast shaft B, and thus the air, after traversing the whole of the workings, ascends the shaft B.

What is technically called the choke damp is not of so dangerous a character as the fire damp, its presence being more easily ascertained, as it immediately extinguishes the lights; it has the effect of preventing animal respiration. During gales of wind, or when the atmosphere is particularly dense, the ventilation of the mines is attended with more difficulty, and frequently in those exigencies the men are obliged to strike off work.—It is obvious that the above system of ventilation is attended with great labour and expense, not only from the number of hands employed to superintend the wastes and workings of the mine, but from the quantity of brattices which are incessantly required to stop the new ways, and where a communication must be held with the interior of the colliery. Doors at various distances are made, at each of which is placed a boy to permit the ingress and egress of the corves or baskets which contain the coal; the least negligence in closing one of these doors might be attended with serious consequences, as by changing the route of the current of air, and thus leaving unventilated a certain district of the mine, the hydrogen gas would accumulate, and upon the introduction of a candle immediately explode; from this circumstance many accidents have arisen, as no caution had been considered necessary where no danger was apprehended.

MINERAL WATERS. See WATERS.

MINERALOGY, is that science which treats of the solid and inanimate materials of which our globe consists; and these are usually arranged under four classes: the earthy, the saline, the inflammable, and the metallic, which are thus distinguished: 1. The earthy minerals compose the greater part of the crust of the earth, and generally form a covering to the rest. They are not remarkable for being heavy, brittle, or light-coloured. They are little disposed to crystallize, are uninflamable in a low temperature, insipid, and without much smell. 2. The saline minerals are commonly moderately heavy, soft, sapid, and possess some degree of transparency. 3. The inflammable

class of minerals is light, brittle, mostly opaque, of a yellow, brown, or black colour, seldom crystallize, and never feel cold. 4. Metallic minerals are characterized by being heavy, generally opaque, tough, malleable, cold, not easily inflamed, and by exhibiting a great variety of colours, of a peculiar lustre. Under each of these classes are various genera, species, subspecies, and kinds, which it would far exceed the limits of our Dictionary to notice, and which are only properly described in very voluminous works on this particular branch of science. See GEOLOGY. We shall describe the external characters, which are of the first importance in facilitating our acquaintance with minerals. These are either generic or specific. The generic are certain properties of minerals, without any reference to their differences, as colour, lustre, weight, &c.; and the differences between these properties form the specific characters. Generic characters may be general or particular. In the first division are comprehended those that occur in all minerals, in the last those that are found only in particular classes of minerals. The particular generic external characters are thus advantageously arranged: 1. Colour. 2. Cohesion of particles distinguished into solid, friable, and fluid. In solid minerals are to be regarded the external shape, the external surface, and the external lustre. When broken, the lustre of the fracture, the fracture itself, and the shape of the fragments, are to be noticed. In distinct concretions, regard must be paid to the shape of the concretions, their surface, their lustre, transparency, streak, and soiling. All these may be ascertained by the eye. By the touch, we may discover the hardness of minerals, their tenacity, frangibility, flexibility, their unctuousity, coldness, weight, and their adhesion to the tongue. By the ear we distinguish their sound, and by the smell and taste the qualities which these two senses indicate. In friable minerals, external shape, lustre, aspect of particles, soiling, and degree of friability, are to be attended to. In fluid minerals, the lustre, transparency, and fluidity, are principal objects to be regarded. The specific external characters of minerals are founded on the distinctions and varieties of the two great generic divisions. And first, of colours, the names of which are derived from certain bodies in which they most generally occur, either in a natural or artificial state, or from different mixtures and compositions of both.

1. Colour.—1. White. This may be snow-white, reddish-white, yellowish white, silver-white, grayish-white, greenish-white, milk-white, or tin-white. 2. Gray. Lead-gray, bluish-gray, pearl-gray, reddish-gray, smoke-gray, greenish-gray, yellowish-gray, steel-gray, and ash-gray. 3. Black. Grayish-black, brownish-black, dark-black, non-black, greenish-black, and bluish-black. 4. Blue. Indigo-blue, Prussian-blue, lavender-blue, smalt-blue, sky-blue. 5. Green. Verdigris-green, celadon-green, mountain-green, emerald-green, leek-green, apple-green, grass-green, pistachio-green, asparagus-green, olive-green, blackish-green, canary-green. 6. Yellow. Sulphur-yellow, lemon-yellow, gold-yellow, bell-metal-yellow, straw-yellow, wine-yellow, Isabella-yellow, ochre-yellow, orange-yellow, honey-yellow, wax-yellow, brass-yellow. 7. Red. Morning-red, hyacinth-red, brick-red, scarlet-red, copper-red, blood-red, carmine-red, cochineal-red, crimson-red, columbine-red, flesh-red, rose-red, peach-blossom-red, cherry-red, brownish-red. 8. Brown. Reddish-brown, clove-brown, hair-brown, yellowish-brown, tobacco-brown, wood-brown, liver-brown, blackish-brown. Besides these distinctions, colours may be clear, dark, light, or pale; they may have a tarnished appearance, a play, a changeability, an iridescent, an opalescence, a permanent alteration, and a delineation of figure or pattern, such as dotted, spotted, clouded, flamed, striped, veined, dendritic, or uniform.

11. *Cohesion of Particles.*—Minerals are divided into, 1. Solid, or such as have their parts coherent, and not easily moveable; 2. Friable, or that state of aggregation in which the particles may be overcome by simple pressure of the finger; and, 3. Fluid, or such as consist of particles which alter their place in regard to each other by their own weight.

1. Solid Minerals.—External aspect has three things to be regarded, 1. The shape; 2. The surface; and, 3. The lustre. The external shape again may be common, particular, regular, or extraneous; and hence arises the specific differences. 1.

The common external shape may be massive, disseminated coarsely, minutely, or finely; in angular pieces, sharp-cornered or blunt-cornered; in grains, large, coarse, small, fine, angular, flat, round; in plates, thick or thin; in membranes or flakes, thick, thin, or very thin. The particular external shape may be longish, as dentiform, filiform, capillary, reticulate, dendritic, coralliform, stalactitic, cylindrical, tubiform, claviform, or fruticose; roundish, as globular, spheroidal, ovoidal, spheroidal, amygdaloidal, reniform, tuberosc, or fused-like; flat, as specular, or in leaves; cavernous, as cellular in various forms, with impressions, perforated, corroded, amorphous, or vesicular; entangled, as ramose, &c. In the regular external shape or crystallization are to be regarded its genuineness, according to which it may be either true or supposititious; its shape, made up of planes, edges, angles, in which are to be observed the fundamental figure and its parts, the kind of fundamental figure, the varieties of each kind of fundamental figure with their accidents and distinctions, and the alterations which the fundamental figure undergoes by truncation, by bevelment, by acumination, or by a division of the planes. These are a variety of figures under each of these sub-divisions. It must be remarked also that the external shape may be extraneous, or derived from the animal and vegetable kingdoms, as in fossils and petrifications. 2. The external surface contains several varieties of distinctions. It may be uneven, granulated, rough, smooth, or streaked in various ways and directions. 3. The external lustre is the third generic external character, and is of much importance to be attended to. In this we have to consider the intensity of the lustre, whether it is splendid, shining, glistening, glimmering, or dull; next the sort of lustre, whether metallic or common. The latter is distinguished into semi-metallic, adamantine, pearly, resinous, and vitreous.

Aspect of the Fracture of Solid Minerals.—After the external aspect, the fracture forms no inconsiderable character in minerals. Its lustre may be determined as in the external lustre; but the fracture itself admits of great varieties. It may be compact, splintery, coarsely splintery, finely splintery, even, conchoidal, uneven, earthy, hackly. If the fracture is fibrous, we are to consider the thickness of the fibres, if coarse or delicate, the direction of the fibres, if straight or curved; and the position of the fibres, if parallel or diverging. In the radiated fracture we are to regard the breadth of the rays, their direction, their position, their passage or cleavage. In the foliated fracture, the size of the folia, their degree of perfection, their direction, position, aspect of their surface, passage or cleavage, and the number of cleavages, are to be noted. The shape of the fragments may also be very various, regular, as cubic, rhomboidal, trapezoidal, &c., or irregular, as cuneiform, splintery, tabular, indeterminate angular.

Aspect of the distinct Concretions.—The aspect of the distinct concretions forms very prominent external characters. They may be granular, different in shape, or in magnitude; they may be lamellar, distinct, concretionary, differing in the direction of the lamellæ, in the thickness, with regard to shape, and in the position. The surface of the distinct concretions may be smooth, rough, streaked, or uneven; as for their lustre, it may be determined in the same manner as the external lustre.

General Aspect as to Transparency.—Minerals, as is well known, have different degrees of transparency, which may be considered among their external characters. They may be transparent, semitransparent, translucent, translucent at the edges, or opaque.

The Streak.—The colour of this external character may be either similar or different. It is presented to us when a mineral is scraped with the point of a knife; and is similar, when the powder that is formed is of the same colour with the mineral, as in chalk; or dissimilar or different, as in cinnabar, orpiment, &c.

The Soiling or Colouring.—Is ascertained by taking any mineral substance between the fingers, or drawing it across some other body. It may soil strongly, as in chalk; slightly, as in molybdena; or not at all, which is a quality belonging to most of the solid minerals. All the preceding external characters are recognized by the eye.

External Characters from the Touch.—These are eight in number, and are not destitute of utility to the mineralogical student. 1. Hardness; 2. Tenacity; 3. Frangibility; 4. Flexibility; 5. Adhesion to the tongue; 6. Unctuousity; 7. Coldness; 8. Weight. Hardness may be tried by a capacity to resist the file, yielding a little to it, by being semi-hard, soft, or very soft. Tenacity has different degrees, in substances being brittle, sectile or mild, or ductile. The frangibility consists in minerals being very difficultly frangible, easily frangible, or very easily frangible. The flexibility is proved by being simply flexible, elastically flexible, commonly flexible, or inflexible. The adhesion to the tongue may be strongly adhesive, pretty strongly, weakly, very weakly, or not at all. Unctuousity may be meagre, rather greasy, greasy, or very greasy. Coldness is subdivided into cold, pretty cold, rather cold. Weight may be distinguished into swimming or supernatant, light, rather light, heavy, very heavy. The three last divisions from the touch, are in the Wernerian system regarded as anomalous; but they seem properly to be classed under this head.

External Characters from the Sound or Hearing.—The different kinds of sound which occur in the mineral kingdom are, 1. A ringing sound, as in native arsenic and thin splinters of hornstone; 2. A grating sound, as in fresh-burnt clay; 3. A creek ing sound, as that of natural amalgam.

2. Friable Minerals.—The external characters drawn from minerals of this class, are derived, first, from the external shape, which may be massive, disseminated, thinly coating, spumous, or dendritic; secondly, from the lustre, regarded under its intensity, whether glimmering or dull, and its sort, whether common glimmering or metallic glimmering; thirdly, from the aspect of the particles, as being dusty or scaly; fourthly, from soiling or colouring, as strongly or lightly; and lastly, from the friability, which may be loose or cohering.

3. Fluid Minerals.—Of external characters drawn from fluid minerals, there are only two kinds, which include three varieties: 1. The lustre, which is either metallic, as in mercury; or resinous, as in rock oil. 2. The transparency, which is transparent, as in naphtha; turbid, as in mineral oil; or opaque, as in mercury. 3. The fluidity, which may be fluid, as in mercury; or viscid, as in mountain tar.

External Characters from the Smell.—These may be spontaneously emitted and described as bituminous, faintly sulphurous, or faintly bitter; or they may be produced by breathing on, and yield a clay-like smell; or they may be excited by friction, and smell urinous, sulphureous, garlic-like, or empyreumatic.

External Character from the Taste.—This character prevails chiefly in the saline class, and it contains the following varieties: a sweetish taste, sweetish astringent, styptic, salty bitter, salty cooling, alkaline, or urinous.

Having now given a synoptical view of the external characters of minerals, we shall proceed to their classification, and in this we shall chiefly follow the names and arrangement of Professor Jameson.

CLASS I. Earthy Fossils.—Genus I. Diamond. This precious stone has great variety of shades, exhibiting a beautiful play of colours. It occurs in angular and spherical grains, which present planes of crystallization, or are actually crystallized. Its fundamental crystal is the octahedron, which passes into various forms. It is hard, brittle, frangible, and has a specific gravity of 3.600. The diamond has, by modern experiments, been proved to be nearly pure carbon, and begins to burn at 14 deg. or 15 deg. of Wedgewood.

Genus II. Zircon.—Species 1. Zircon; which see. 2. Hyacinth. A rectangular four-sided prism, flatly acuminate by four planes, set in the lateral edges. Of this figure, however, several varieties occur. Crystals generally small, and always imbedded: the lateral planes smooth, externally shining; internally splendid and glassy, inclining somewhat to resinous.

Genus III. Flint.—Species 1. Chrysoberul. General colour asparagus-green, passing into a variety of allied shades. It exhibits a milk-white light; occurs in roundish and angular grains, which sometimes approach in shape to the cube. It is seldom crystallized; but when in this state, it presents a long six-sided table, having truncated lateral edges, and longitudinally streaked lateral planes. The crystals are small, ex-

ternally shining, and internally splendid. It is hard, brittle; not easily frangible, with a specific gravity of 3·600: without addition, infusible. 2, Chrysolite. The colour is pistachio-green, of all degrees of intensity: external surface of the crystals splendid, internally splendid, and vitreous. 3, Olivine. Generally asparagus-green, of various degrees of intensity. It is found imbedded also in round pieces and grains; when crystallized, which is rare, in rectangular four-sided prisms. Internally shining, varying between glistening and splendid; semitransparent, easily frangible; in a low degree hard, and not particularly heavy. It is nearly fusible without addition. Occurs imbedded in basalt. 4, Augite. Colour blackish-green. It occurs chiefly in indeterminate angular pieces and roundish grains. Occasionally crystallized, and presents broad rectangular six-sided prisms. The crystals are mostly small. Internally the lustre is shining, approaching sometimes to splendid. The augite is only translucent, and but faintly transparent. It is hard, not easily frangible, and not particularly heavy. It is found in basalt, either singly, or accompanied with olivine. 5, Vesuvianite. Its principal colour is dark olive-green, passing into other allied shades. It occurs massive, and often crystallized in rectangular four-sided prisms. The crystals are mostly short, and placed on one another. The vesuvianite is translucent, hard in a moderate degree, and approaching to heavy. Before the blowpipe it melts without addition. It is found among the exuviae of Vesuvius, whence it derives its name; in Siberia and Kamtschatka. 6, Leuzite. In colour yellowish and grayish-white. It occurs mostly in original round and angular grains. It exhibits acute double eight-sided pyramids. Internally it is shining, approaching to glistening, with a vitreous lustre, inclining somewhat to resinous. The leuzite is translucent and semitransparent; hard in a low degree, brittle, easily frangible, and not very heavy. With borax, it forms a brownish transparent glass. It is found in rocks of the newest floetz trap formation, particularly in basalt. 7, Melanite. In colour velvet-black. It occurs crystallized in a six-sided prism. The crystals are middle-sized or small. Externally they are smooth and shining, approaching to splendid; internally shining, inclining to glistening. The melanite is opaque, hard, pretty easily frangible, and not very heavy. It occurs imbedded in rocks of the newest floetz trap formation. 8, Garnet; see GARNET. 9, Pyrope. Colour dark blood-red. It occurs in small and middle-sized, roundish, and angular grains; but never crystallized. Its lustre is splendid and vitreous. It is completely transparent, hard so as to scratch quartz. It is found imbedded in Scotland, in sand, on the sea shore. It is employed in various kinds of jewellery, and is generally set in a gold foil. 10, Grenatite. Colour a dark reddish-brown. It is always crystallized in broad six-sided prisms. The crystals small and middle-sized, internally glistening, with a lustre between vitreous and resinous. It varies from opaque to translucent, is hard, brittle, easily frangible, and not particularly heavy. It is found imbedded in mica slate. 11, Spinelite. The predominant colour is red, which passes on into blue, green, yellow, and brown. It occurs in grains, and likewise crystallized in octahedrons, with several variations. Externally and internally the lustre is splendid and vitreous. It is fusible with borax: occurs in rocks belonging to the newest floetz trap formation. It is used as a precious stone. 12, Sapphire. The principal colour Berlin blue: but it is found also red, with the intermediate shades of these two colours. It occurs in small rolled pieces, and crystallized in double three-sided pyramids. The crystals are small and middle-sized. Internally the lustre is splendid and vitreous. Some varieties, when cut, exhibit a star of six rays. The sapphire is hard in the highest degree, but yields to the diamond: it is easily frangible; specific gravity of about 4·000. It is fusible without addition: occurs in rocks of the newest floetz trap formation. This precious stone is found in the utmost beauty in Pegu and Ceylon. 13, Corundum; see CORUNDUM. 14, Diamond Spar. The colour is a dark hair-brown. It occurs massive, disseminated, in rolled pieces, and crystallized in six-sided prisms, or very acute six-sided pyramids. Internally, its lustre is splendid: translucent on the edges, hard in a high degree, easily frangible. It has hitherto been found only in China. Both this stone and corundum are em-

ployed in cutting and polishing hard minerals, and they seem to be nearly allied to each other. 15, Emery; see EMERY. 16, Topaz. The chief colour is a wine-yellow, of all degrees of intensity. It is found massive, disseminated, and sometimes rolled, but most commonly crystallized in oblique eight-sided or four sided prisms, which exhibit several varieties. The crystals are small and middle-sized, externally splendid; internally splendid and shining; lustre vitreous. The topaz alternates from translucent to transparent, and is duplicating transparent. It is hard in a high degree, easily frangible, and is not particularly heavy. It is fusible with borax; and some kinds in a gentle heat turn white, and are sometimes sold for diamonds. It is commonly found in veins that traverse primitive rocks. 17, Emerald; which see. 18, Beryl; see BERYL. 19, Schorl. Divided into two sub-species, common schorl and tourmaline. 20, Thumerstone. Colour commonly clove-brown, of various degrees of intensity. It is occasionally found massive, more frequently disseminated: but generally crystallized in very flat and oblique rhombs. Externally, its lustre is splendid; internally, it alternates from glistening to shining, and is vitreous. This species alternates from perfectly transparent to weakly translucent. It appears to be peculiar to the primitive mountains. 21, Iron Flint. The colour a yellowish-brown, bordering on liver-brown. It occurs commonly massive, but also crystallized in small equiangular six-sided prisms. Externally, its lustre is splendid, internally shining, and is intermediate between vitreous and resinous. It is opaque, and slightly translucent on the edges. It is pretty hard, somewhat difficultly frangible, and approaching to heavy. It occurs in iron-stone veins, and renders the ore very difficult of fusion. 22, Quartz. Werner divides this into five sub-species: amethyst, rock-crystal, milk-quartz, common quartz, and prase. 23, Hornstone; which see. 24, Flint. Colour gray, but with many varieties. It occurs massive, in regular plates, in angular grains, in globular and elliptical rolled pieces, in the form of sand, and tubercles and perforated. Sometimes it is crystallized, in double six-sided prisms, or flat double three-sided pyramids. Internally, the lustre is glimmering, translucent on the edges, hard, easily frangible, and not particularly heavy. 25, Chalcedony. Divided into two sub-species, chalcedony and cornelian; which see. Agate. The fossils known under this name are all compound substances; and hence cannot have a particular place in any systematic arrangement. Werner, therefore, has placed them as a supplement to the species chalcedony, which forms a principal constituent part of them. See AGATE. 26, Heliotrope; which see. 27, Plasma. The colour intermediate between grass and leek-green, and of different degrees of intensity. It occurs in indeterminate angular pieces which have a rough earthy crust. Internally its lustre is glistening. It is intermediate between semi-transparent and strongly translucent, hard, brittle, frangible without great difficulty, and not particularly heavy. 28, Chrysopras. 29, Flinty Slate. This has been divided into two sub-species, common flinty slate and Lydian stone. 30, Cat's Eye. The colour gray, with many varieties. It occurs in blunt-edged pieces, in rolled pieces, and likewise massive. Internally shining; usually translucent, and sometimes also semi-transparent. It is hard, easily frangible, and not particularly heavy. Its geognostic situation is unknown. It is imported from Ceylon and the coast of Malabar; and is usually cut for ring-stones. Some of the varieties are highly valued. 31, Prehnite. Colours various shades of green, white, and yellow. It is sometimes massive, and sometimes crystallized in oblique four-sided tables. Externally, the crystals are smooth and shining; internally, inclining to glistening and pearly. It is translucent, sometimes passing into semi-transparent, and transparent: it is hard, easily frangible, and not very heavy. 32, Zeolite. This species is divided into five sub-species: 1. Mesaly; 2. Fibrous; 3. Radiated; 4. Foliated; 5. Cubic-zeolite. 33, Cross-Stone. The colour is a grayish-white. It occurs crystallized either in broad rectangular four-sided prisms, or is twin crystals. Internal and external lustre is shining, inclining to splendid or glistening. The cross-stone is translucent, passing to transparent, semi-hard, easily frangible, and not particularly heavy. It has hitherto been found only in mineral veins, and in agate balls. 34, Agate-Stone. Colour a perfect

azure blue, of different shades. It is found massive, disseminated, and in rolled pieces. The lustre is glistening and glimmering. It is translucent on the edges, pretty hard, brittle, easily frangible, and not particularly heavy. See AGATE.

Genus IV. Clay.—Species 1, Jasper. 2, Opal. 3, Pitch Stone. 4, Obsidian. 5, Pearl Stone. 6, Pumice Stone. 7, Felspar. Divided into four sub-species; compact, common, adularia, and Labrador stone. 8, Pure Clay. Snow white, with occasionally a yellowish tinge, it occurs in kidney-shaped pieces, which have no lustre. It is opaque, soils very little, adheres slightly to the tongue, is light, and intermediate between soft and friable. Pure clay is found immediately under the soil, accompanied with foliated gypsum and selenite, at Halle, in Saxony, only. 9, Porcelain Earth. 10, Common Clay. Divided into six sub-species: 1. Loam; 2. Potters' clay is of two kinds, earthy and slaty; 3. Pipe clay; 4. Variegated clay, commonly white, red, and yellow, striped, veined, and spotted: it occurs massive, is soft, passing into friable, feels a little greasy, and adheres somewhat to the tongue; 5. Clay-stone, commonly gray or red, with various intermediate tints; 6. Slate clay. 11, Polier, or Polishing-stone. 12, Tripoli. 13, Alum Stone. 14, Alum Earth. 15, Alum Slate. 16, Bituminous Shale. 17, Drawing Slate, or Black Chalk. Its colour is a grayish-black, with a tinge of blue; it occurs massive, is opaque, colours and writes, is soft, mild, easily frangible, feels meagre but fine, and is rather light: it is found in primitive mountains in France, Germany, Iceland, Scotland, and the Hebrides. When of a middling degree of hardness, it is used for drawing. 18, Whet Slate. 19, Clay Slate. 20, Lepidolite. Colour a kind of peach-blossom, it occurs massive. Internal lustre glistening; it is translucent, soft, easily frangible, and easily melts before the blowpipe. Hitherto it has only been found in Moravia, where it lies in gneiss. 21, Mica, or Glimmer. 22, Pot Stone. 23, Chlorite, which see. 24, Hornblende. 25, Basalt. 26, Wacke. 27, Clink Stone. Commonly of a dark greenish-gray colour, massive, in regular columns, and tabular distinct concretions, usually translucent on the edges, brittle, easily frangible, and when struck with a hammer sounding like a piece of metal. It is said to belong to the floetz trap formation, and generally rests on basalt. 28, Lava. Divided into two sub-species; Stag-lava and Toam-lava. 29, Green Earth. Its colour is a celaden-green, of various degrees of intensity: it occurs massive, in angular and globular pieces, and also disseminated. Internally it is dull, streak glistening, very soft, easily frangible, and light. It is principally found in amygdaloid, in Saxony, Bohemia, Scotland, and other places, and is used by painters. 30, Lithomarge. Divided into two sub-species; friable and indurated. 31, Rock Soap. 32, Yellow Earth. To the clay genus, likewise, belong adhesive slate, float-stone, pinites, and amber.

Genus V. Talc.—Species 1, Bole. 2, Native Talc Earth. 3, Meerschaut. 4, Fullers' Earth. 5, Neaphrite. 6, Steatite. 7, Serpentine, which see. 8, Schiller Stone. 9, Talc. 10, Asbest. See ASBESTOS. 11, Cyanite, which see. 12, Actynolite. Is divided into the following sub-species: 1. Asbestous actynolite is of a greenish-gray colour, occurs massive, disseminated, and in capillary crystals; is internally glistening, translucent on the edges, soft, brittle, not easily frangible, not particularly heavy: it is found in mineral beds in Saxony, and other parts of Germany. 2. Common actynolite is generally of a green leek colour, passing into other shades of the same; it occurs massive, and likewise crystallized in very oblique six-sided prisms, is splendid externally, semi-hard, rather brittle, and not easily frangible: it is found in beds in primitive mountains, in Saxony, Switzerland, Norway, and Scotland. 3. Glassy actynolite is principally of a mountain green colour, of various degrees of intensity.

Genus VI. Calc.—Species 1, Rock Milk. 2, Chalk. Colour principally of a yellowish-white: it occurs massive, disseminated, and as crust over flint. 3, Lime-stone. Divided into several sub-species: viz. compact, foliated lime-stone, fibrous lime-stone, and pea-stone. 4, Schaum, or foaming Earth. 5, Slate spar. 6, Brown spar. 7, Rhomb spar. 8, Schaalstone. 9, Stink-stone. 10, Marble. 11, Bituminous marble slate. Colour intermediate between grayish and brownish-black; it is massive, from glimmering to shining, fragments slaty, usually soft,

not very brittle, easily frangible, and streak shining: it is found in beds along with the oldest floetz lime-stone, and contains much copper intermixed with it, on account of which it is usually smelted in Thuringia. 12, Calc tuff. 13, Arragonite. Principal colours are greenish-gray and iron-gray: it occurs crystallized in perfect equiangular six-sided prisms; the lustre is glistening, passing into shining, and is vitreous; it is semi-hard, brittle, not particularly heavy. It was first discovered in the province of Arragon, whence its name, imbedded in gyps. 14, Appatite. Colours white, green, blue, and red; it generally occurs crystallized, the radical form of which is the equiangular six-sided prism. Externally it is splendid, internally shining and resinous: it is commonly transparent, semi-hard, brittle, easily frangible, and occurs in thin veins, &c. 15, Asparagus, or spargel stone. 16, Boracite. Its colours are yellowish, smoke and grayish-white, passing to asparagus green; it occurs in crystallized cubes, with the edges and angles truncated, internally shining, commonly semi-transparent, semi-hard, brittle, and easily frangible. 17, Fluor. See FLUOR. 18, Gyps. This is divided into the following sub-species: 1. Gyps earth, of a yellowish-white colour, passing into some allied shades, is intermediate between fine scaly, and dusky, dull, and feebly glimmering, soils a little, feels meagre but soft and fine, and is light; it is found, though rarely, in gyps countries. 2. Compact gyps, is commonly ash-gray, passing into smoke and yellowish-gray, is massive, internally dull, feebly translucent on the edges, very soft, frangible without great difficulty, and is employed in architecture and sculpture, under the name of alabaster. 3. Foliated gyps is commonly white, gray, or red, presenting spotted, striped, and veined colour delineations. 4. Fibrous gyps is principally white, gray, and red, with various shades of each. Gyps, when burnt, forms an excellent cement, and is used for many ornamental purposes. 19, Selenite. 20, Cubo spar.

Genus VII. Baryte.—Species 1, Whitherite. 2, Heavy spar or baryte.

Genus VIII. Strontian.—Species 1, Strontian. 2, Celestine. Divided into two sub-species: 1. Fibrous celestine, is of an intermediate colour, between indigo blue and bluish-gray; it occurs massive and in plates, and also crystallized, showing a tendency to prismatic distinct concretions; it is translucent, soft, or semi-hard, easily frangible, and pretty heavy. 2. Foliated celestine, is of a milky-white colour falling into blue; it occurs massive, and also crystallized in six-sided tables, intersecting each other; it has a glistening lustre, is strongly translucent, softish, not particularly brittle, easily frangible, and hard. It occurs sometimes in sulphur beds, and is found very finely crystallized in Sicily, and near Bristol.

CLASS II. Fossil Salts.—The substances included in this class are confined to those which are found in a natural state only; and the greater part of them appear to be formed by the agency of water, air, &c. The distinguishing characters of fossil salts are, their taste and easy solution. They resemble each other so closely, that the term *saline consistence* is used to express whatever relates to hardness, tenacity, and frangibility.

Species 1, Natron, or natural soda. 2, Natural nitre. 3, Natural rock-salt. 4, Natural sal-ammoniac. 5, Natural Epsom salt. 6, Natural Glauber salt. 7, Natural alum. 8, Hair salt. 9, Rock butter. Colour light yellow, or grayish-white; it occurs massive and tuberoso, is translucent, has a saline consistence, a sweetish sour astringent taste, and feels a little greasy. It oozes out of fissures of rocks of alum slate, and is found in Lusatia, Thuringia, Denmark, Siberia, and near Paisley in Scotland. 10, Natural vitriol. Divided into the sub-species: iron, copper, and zinc vitriol. Borax, though so well known by name, is without a place in the Wernerian system, as it is uncertain whether or not it occurs in a solid state; most probably it occurs only in solution in certain lakes. The new genus stallite, of which only one species, cryolite, has been found in Greenland, comes under this head.

CLASS III. Inflammable Fossils.—Fossils belonging to this class are light, brittle, mostly opaque, yellow, brown, or black, seldom crystallized, and never feel cold. They are more nearly allied to the metallic than to the earthy or saline classes.

Genus I. Sulphur.—Species 1, Natural sulphur.

Genus II. Bituminous.—See BITUMEN and COAL.

Genus III. Graphite.—Species 1, Glance coal. Divided into two sub-species: conchoidal and slaty. 2, Graphite, containing two sub-species, scaly and compact graphite. 3, Mineral charcoal. Colour a grayish-black: it occurs in small angular and somewhat cubical-shaped pieces, is glimmering, with a silky lustre, soils strongly, is soft, and light. It is found in thin layers in different kinds of coal, and is widely disseminated.

Genus IV. Resin.—Species 1, Amber; which is divided into the sub-species: 1. White; 2. Yellow amber. 2, Honey-stone. Mellite.

CLASS IV. *Metallic Fossils*.—Genus I. Platina. Species 1, Native platina.

Genus II. Gold.—Species 1, Native gold. Divided into three sub-species: 1. Gold-yellow native gold; 2. Brass-yellow native yellow; 3. Grayish-yellow native gold.

Genus III. Mercury.—Species 1, Native mercury, or quick-silver. 2, Natural amalgam. 3, Mercurial horn-ore, or corneous mercury. 4, Mercurial liver ore, or mercurial hepatic ore. 5, Cinnabar.

Genus IV. Silver.—Species 1, Native silver. 2, Antimonial silver. 3, Arsenical silver. 4, Corneous silver ore, or horn ore. 5, Silver black. 6, Silver glance. 7, Brittle silver glance. 8, Red silver ore. 9, White silver ore. 10, Black silver ore.

Genus V. Copper.—Species 1, Native copper. 2, Copper glance. 3, Variegated copper ore. Colour, when dug, intermediate between copper-red and pinchbeck-brown, but it soon becomes tarnished: it occurs massive, disseminated in plates, membranes, and crystallized in octahedrons. 4, Copper pyrites. 5, White copper ore. 6, Gray copper ore, or Fahs ore. Common colour steel-gray: it occurs massive, disseminated, and also crystallized in tetrahedrons, octahedrons, and garnet dodecahedrons. 7, Copper black. 8, Red copper ore. 9, Tile ore. 10, Copper azure. 11, Melachite. 12, Copper green. Colour verdigris green, of different degrees of intensity. 13, Iron-shot copper green. 14, Copper emerald. 15, Copper mica. Emerald-green colour: it occurs massive, disseminated, and occasionally crystallized in very thin six-sided tables; it is soft, sectile, not very brittle, nor particularly heavy; and has hitherto been found only in veins in Cornwall, where it passes under the unscientific name of foliatic arseniate of copper. 16, Lenticular ore. 17, Olive ore. Mountain blue.

Genus VI. Iron.—Species 1, Native iron. Is of a light steel-gray colour, inclining to silver-white: it has hitherto been found only ramose; internally it is intermediate between glimmering and glistening, with a perfect metallic lustre, and a hackly fracture: it is between soft and semi-hard, perfectly malleable, common, flexible, difficultly frangible, and uncommonly heavy. Hitherto it has been found only in loose masses on the surface of the earth, and is a rare production. 2, Iron pyrites. 3, Magnetic pyrites. 4, Magnetic iron-stone. Common magnetic iron-stone is of an iron black-colour: is massive, disseminated, and also crystallized in cubes, octahedrons, and garnet dodecahedrons, and rectangular four-sided prisms. It is extremely shining; internally between splendid and glistening, with a metallic lustre; is intermediate between hard and semi-hard, brittle and heavy. It occurs most frequently in primitive mountains. When pure it affords most excellent bar iron. 5, Iron glance. Common iron glance is usually of a dark steel-gray colour, with several different shades; it commonly occurs massive and disseminated, and also crystallized in flat, double, three-sided pyramids, and in double three-sided pyramids. It offers, when smelted, an excellent malleable iron. 6, Red iron-stone. Red iron froth. The colour is intermediate between cherry-red and brownish-red; it occurs commonly friable, massive, sometimes coating and disseminated, and is composed of scaly particles, which are glimmering, and have a semi-metallic lustre. 7, Brown iron-stone. Brown iron froth is of an intermediate colour between steel-gray and clove-brown, and is between friable and solid; it occurs massive, coating, spumous, &c., and is composed of scaly particles, shining and glistening, with a metallic lustre. It soils strongly, feels greasy, and is very light. It is commonly found lining dusty cavities. 8, Sparry iron-stone. The principal colour is a light yellowish-gray, which, on exposure to the air or heat, changes into brown or black; it occurs massive, disseminated with pyramidal im-

pressions, in plates, and crystallized. It is chiefly confined to the primitive and floetz mountains. 9, Black iron-stone. 10, Clay iron-stone. Reddle is of a light brownish-red, passing into a cherry-red: it occurs only massive; soils strongly, and writes, is sectile, easily frangible, and rather heavy. It is chiefly found in the newer clay-state, in Germany and Siberia. The coarser varieties are used by the carpenter, the finer by the painter, under the name of red chalk. 11, Bog iron ore. 12, Blue iron-earth. 13, Green iron-earth. Friable green iron-earth is of a siskin-green colour; occurs massive and disseminated, is more or less cohering, soft, fine, easily frangible, and intermediate between particularly heavy and heavy. 14, Cube ore.

Genus VII. Lead.—Species 1, Lead glance. Common lead glance is of a fresh lead-gray colour, of different degrees of intensity; it occurs massive, disseminated, in membranes, &c., and also crystallized in cubes, octahedrons, four-sided prisms, six-sided prisms, and three-sided tables. It is soft, sectile, externally easily frangible, and uncommonly heavy, and is found in veins and beds in primitive, transitive, and floetz mountains. It is most frequently worked as an ore of lead, but sometimes as an ore of silver. 2, Blue lead ore. 3, Brown lead ore. 4, Black lead ore. 5, White lead ore. 6, Green lead ore. 7, Red lead ore. 8, Yellow lead ore. 9, Lead vitriol, or vitriol of lead. 10, Lead earth.

Genus VIII. Tin.—Species 1, Tin pyrites. 2, Tin stone. 3, Cornish tin ore, or wood tin.

Genus IX. Bismuth.—Species 1, Native bismuth. 2, Bismuth glance, of a light-gray lead-colour. 3, Bismuth ochre, of a straw-yellow colour passing into other neighbouring shades.

Genus X. Zinc.—Species 1, Blende. 2, Calamine.

Genus XI. Antimony.—Species 1, Native antimony. 2, Gray. 3, Black. 4, Red. 5, White antimony ore. 6, Antimony ochre.

Genus XII. Cobalt.—Species 1, White cobalt ore. 2, Gray cobalt ore. 3, Cobalt glance. The colour is of a silver-white, slightly inclining to reddish: it is commonly massive and disseminated, sometimes crystallized in different forms: is externally splendid, internally between shining and glistening, and has a metallic lustre. It is semi-hard, brittle, not very easily frangible; and when struck with steel, emits an arsenical smell. It is found in veins in various formations, in the different mine countries of the continent of Europe; and from it the greatest part of the cobalt in commerce is obtained, which is highly useful in the manufacture of glass, and as a pigment. 4, Black cobalt ore. 5, Brown cobalt ochre. 6, Yellow cobalt ochre. 7, Red cobalt ochre.

Genus XIII. Nickel.—Species 1, Copper nickel. 2, Nickel ochre.

Genus XIV. Manganese.—The three species are, 1. Gray; 2. Black; 3. Red manganese ore.

Genus XV. Molybdena.—Species 1, Molybdena.

Genus XVI. Arsenic.—Species 1, Native arsenic. 2, Arsenic pyrites. 3, Orpiment. 4, Arsenic bloom.

Genus XVII. Scheele.—Species 1, Tungsten. 2, Wolfram.

Genus XVIII. Menachine.—Species 1, Menachanite. 2, Octahedrite. 3, Rutile. 4, Nigrine. 5, Iserine.

Genus XIX. Uran.—Species 1, Pitch ore. 2, Uran mica. 3, Uran ochre.

Genus XX. Sylvan.—Species 1, Native sylvan. 2, Graphite ore. 3, Yellow sylvan ore. 4, Black sylvan ore.

Genus XXI. Chroma.—Species 1, Acicular, or needle ore. Its colour is dark steel-gray: occurs in imbedded acicular crystals; internally shines with a metallic lustre, is soft, not very brittle, heavy, and is always accompanied with chrome ochre, and sometimes with native gold. It is found in Siberia. 2, Chrome ochre. It is of a verdigris green, passing through several neighbouring shades: it occurs massive, disseminated, and in membranes; is dull, soft, not very heavy, and is found with the preceding species.

For the various forms which minerals are found under, see CRYSTALLIZATION.

MINIATURE, a delicate kind of painting distinguished by the smallness of the figures, its being performed with dots or points instead of lines; by the faintness of the colouring; and by its being usually done on vellum. See PAINTING.

MINISTER, in Theology, a person who preaches, performs religious worship in public, administers the sacrament, &c.

MINISTER of State, a person to whom a sovereign prince intrusts the administration of the government.

MINISTER, Foreign, is a person sent into a foreign country to manage the affairs of his province, or of the state to which he belongs. Of these there are two kinds: those of the first rank are ambassadors and envoys extraordinary, who represent the persons of their sovereigns. The ministers of the second rank are the ordinary residents.

MINIUM, in the Arts, red lead and oxide of lead.

MINOR, in Law, is an heir, either male or female, before arriving at the age of twenty-one; during their minority, minors are usually incapable of acting for themselves, in a legal point of view.

MINOR, in Logic, the second proposition of a syllogism.

MINSTREL, in ancient customs, certain persons who combined the character of poet and musician, and whose profession it was to wander about the countries they inhabited, singing panegyric songs and verses on their occasional benefactors, accompanying them with some musical instrument.

MINT, the place in which the king's money is coined. *See* COINAGE. There were anciently mints in almost every county in England; but the only mint at present in the British dominions, is that in the Tower of London. The officers of the mint are, 1. The warden of the mint, who is the chief; he oversees the other officers, and receives the bullion. 2. The master worker, who receives bullion from the warden, causes it to be melted, delivers it to the moneyers; and when it is coined, receives it again. 3. The comptroller, who is the overseer of all the inferior officers, and sees that all the money is made to the just assize. 4. The assay master, who weighs the gold and silver, and sees that it is according to the standard. 5. The two auditors, who take the accounts. 6. The surveyor of the melting, who, after the assay master has made trial of the bullion, sees that it is cast out, and not altered after it is delivered to the melter. 7. The engraver, who engraves the stamps and dies for the coinage of the money. 8. The clerk of the irons, who sees that the irons are clean and fit to work with. 9. The melter, who melts the bullion before it be coined. 10. The provost of the mint, who provides for and oversees all the moneyers. 11. The blanchers, who anneal and cleanse the money. 12. The moneyers; some of whom forge the money, some share it, some round and mill it, and some stamp and coin it. 13. The porters, who keep the gate of the mint.

MINT, was also a pretended place of privilege, in Southwark, near the King's Bench, put down by statute. If any persons, within the limits of the mint, shall obstruct any officer in the serving of any writ or process, &c. or assault any person therein, so as he receive any bodily hurt, the offender shall be guilty of felony, and be transported to the plantations, &c. stat. 9. Geo. I.

Process of Coining at the Royal Mint.—The process of melting silver, at the royal mint, is a recent invention, and a very great improvement. The usual mode was to melt it into black lead pots, and a considerable coinage of tokens for the Bank of Ireland was performed with the meltings done in this way. The importations being entirely Spanish dollars, and the tokens of that standard, the melter could easily melt them in quantities of 60 lbs. troy, which was done. The inconvenience of this mode was severely felt, because ingots of silver of various qualities could not be imported for coinage, from the difficulty of not being able to blend several together in one pot, so as to produce the proper standard of our money. So sensible was government of this imperfection in the mint, that in the year 1777, Mr. Alchorne, then master's assay-master, was sent to visit the mints of Paris, Rouen, Lille, and Brussels, and to collect information as to the arts of coining practised in those mints, and particularly the art of melting silver in large quantities. Alchorne's intimate knowledge of the English mint, together with his extensive knowledge as a practical chemist, well fitted him for the undertaking; and his observations on the coin and coinage of France and Flanders are creditable to both his judgment and knowledge.

It is worthy of remark, that it is on record in the books of the

mint, that in the recoinage of William III. the pots of silver weighed 400 pounds troy and upwards; but every trace as to how this quantity of silver was melted is completely lost; and it is only conjectured that it was done in pots made of wrought iron. But not a vestige of a melting furnace, fitted for such a purpose, is to be found in the Tower, nor a single record of the method then practised.

In 1758 some trials for melting silver in wrought iron pots took place, by means of a blast furnace; but they were found so laborious, inconvenient, and profitless, as to cause the process to be abandoned. In 1787, when some silver was imported into the mint for coinage, new experiments were made by the late deputy master and worker, Mr. Morrison, who conducted the meltings. A blast furnace was again tried and abandoned. He next attempted to melt the silver in large black lead pots, containing from 100 to 120 lbs. troy; but the repeated breaking of the pots, although it was attempted to guard them by outside luting, proved a great interruption to the business, and serious loss to the melter. Trial, indeed, was made with cast-iron pots, but these were found subject to melt, and the iron got mixed with the silver. The work too was continually stopped by the king's assayer, in consequence of the metal not being of the proper standard, it being always refined by the process of melting, and lading it with ladles from the pot.

Independently of these considerations, great difficulty arose at the office in arranging the potting previous to the operation. The practice pursued at the mint to reduce the metal to standard, of combining and blending the various ingots of better and inferior qualities, adding what little portion of alloy or fine metal might be necessary to obtain accuracy, rendered it impossible, where the ingots weighed from 60 to 80 lbs. troy, to put them of a weight not exceeding 100 lbs. It therefore became necessary, in the first place, to reduce the larger description of ingots to a smaller size by melting, and these were again weighed in the office of receipt. Hence a double operation took place, occasioning additional labour, waste, and expense to the melter, and requiring extraordinary trouble and attendance on the part of the office. It was very obvious that this mode of conducting the silver meltings was extremely defective, and was in consequence abandoned. The next experiments made were with a reverberatory furnace, built after the model of those used in the Lille mint. But no better success attended these trials, and the process was, as in former cases, abandoned. The imperfection here arose from the great refinement of the silver in the melting, by the oxidation of the alloy, and which the usage of the British mint does not allow the melter to supply, as in the French mints. In the French mints, as soon as the silver is in fusion, a sample is taken out and assayed, and copper is added in the proportion to the refinement of the melted silver, (which is kept in fusion while the assay is making;) the whole is well stirred, and immediately laded out and cast into bars. In 1795 and 1798, several farther trials were made by Morrison, who was indefatigable in his endeavours to perfect his department, with a view to attain the object so much desired—that of melting large quantities of silver at once, without producing so much waste and refinement in the metal. In those experiments he tried three furnaces, each of a different construction; and though he was much nearer his point, there was still an imperfection, arising from the mode of dipping out the metal from the pot with ladles, which chilled the metal, and rendered the process extremely laborious and tedious.

No new experiments were made until the year 1804. Mr. Morrison having died in 1803, was succeeded by his son in the office of deputy master and worker of the mint. The extreme scarcity and defective state of the silver coin at this time, arising from the defective state of the melting department, urged Morrison to renew the experiments of his father. In following these experiments, Mr. Morrison had in view the construction of a furnace adapted for the use of cast iron pots, the use of pots of a size capable of melting from 400 to 500 lbs. troy, at one charge—the adaption of such machinery as would supersede the clumsy and wasteful process of lading the silver from the pots when melted—and lastly, the introduction of the use of moulds made of cast-iron, in place of those then used in

the mint, and which were made of sand. In all these objects Mr. Morrison, highly to his credit, perfectly succeeded; and the silver melting department of the new mint was constructed according to the furnace first used in the experiments which led to such a satisfactory result. The whole has been in use since 1811, and the department is capable of melting, with ease, 10,000 lbs. troy of silver daily, as was done for several months during the late recoinage (1817). Before we give a description of the apparatus for flattening, rolling, or laminating the silver, we shall proceed to describe the machinery and furnaces of the silver melting department.

The engraving illustrative of this article exhibits a perspective view of the machine for casting ingots of silver.

In the plate, fig. 1, A A are the furnaces in which the metal is melted. These are the air furnaces, built of fire brick, in the usual manner of melting furnaces; but to render them more durable, the brick work is cased in cast-iron plates, which are put together with screws. B B are the covers to the furnace; they are held down to the top plate of the furnaces by a single screw pin for each; and on the opposite side of the cover, a handle *a* is fixed. By pushing this handle, the cover is moved sideways upon its centre pin, so as to remove it from the furnace mouth. A roller is fitted to the cover, to run upon the top plate and render the motion easy.

The interior figure of each furnace is circular, 30 inches deep, and 21 in diameter; the bottom is a grate of cast iron bars (each bar being moveable) to admit the air. Upon the grate is placed a pedestal or stand of cast-iron, of a concave shape, covered an inch thick with coke or charcoal dust, and upon which the pot is placed in which the silver is melted. The pedestal is nearly two inches thick, and is fully two inches broader in diameter than the pot, the object of which is to protect the hip of the pot from the very high heat which the current of air, ascending through the grate, when the furnace is at work, creates, and which would otherwise melt the pot. This precaution is essentially necessary, from the pedestal raising the pot so considerably above the grate, and from its being entirely surrounded by the fire in the furnace. If the furnace, however, is properly managed, there is no risk of melting the pot. On the top or mouth of the pot is placed a muffle, which is a ring of cast iron six inches deep, made to fit neatly into the mouth of the pot; the use of this muffle is similar to that used in melting, gold to give a greater depth of fuel in the furnace than the mere length of the pot, and which gives a greater degree of perfection to the process. The muffle is also extremely convenient, by giving a depth to the pot, if we may so speak, which enables ingots of silver to be charged, which are longer than the depth of the interior of the pot. The top of the ring or muffle is covered with a plate of cast iron, to prevent the fuel from falling into the pot, and secure the metal from the action of the atmospheric air when in fusion. Each furnace has a flue nine inches wide and six inches deep. The flue is four inches from the top of the furnace, and proceeds in a horizontal direction, and extends to the flue C, which is nine inches square, and is carried up in a sloping direction to the stack or chimney, which is 45 feet high from the grate of the furnace.

When the furnace doors, B B, are closed, the current of air which enters at the grate ascends through the body of the furnace, and causes the fuel, which is coke, and which surrounds the melting pot, to burn very intensely. The degree of heat wanted, however, is very nicely regulated by a damper, which is fixed in the flue of each furnace, and exactly fitting the square of the flue, so that any portion of draught can be given to the furnace that may be wanted. The damper is a plate of wrought iron, fixed in a frame, and is easily moved in and out, so as to increase or diminish the size of the flue. It is fixed in the brick-work of the sloping flue C, about 18 inches above the top of the furnace. The furnace doors B have small holes in them to look into the furnace: these are closed by stoppers or plugs of cast iron. When the furnace is put to work, it is lighted by some ignited charcoal being put upon the grate and around the pot (for the pot is always in its place before the fire is lighted); upon the charcoal about three inches deep of coke is put; the door B is shut, and the damper is pulled out about two inches. When the coke is ignited, a similar quantity is put on, and so continued until the furnace is filled with ignited

coke. The object of this precaution is to prevent the cracking of the cast iron pot by being too suddenly heated; and it is generally about two hours before the pot can be brought to a charging heat, to do it with perfect safety. Before the silver is charged, the pot is heated a bright red; it is then examined to see if it has cracked in bringing up, as it is technically called. This is done by placing a cold iron tool of considerable thickness in the centre of the pot, which immediately renders any crack visible to the eye. When satisfied that the pot is sound, the silver is charged into the pot. With the silver is put into the pot a small quantity of coarsely grained charcoal powder, which coats the inner surface of the pot, and prevents the silver from adhering to it. When the silver is brought to the fusing point, the quantity of charcoal is increased, until it is nearly half an inch deep on the surface of the silver, and which keeps the silver as much as possible from the action of the common air, and prevents that destruction of the alloy which would otherwise cause a considerable refinement in the metal. When the silver is completely and properly melted, it is well stirred with an iron stirrer, so as to make the whole mass of one uniform standard quality. The pot is then taken out of the furnace by the crane, and conveyed to the pouring machine, by which its contents are poured into the ingot moulds.

Fig. 2, is the crane, it is supported by a strong column of cast-iron, X, which is firmly fixed in masonry beneath the floor. The gibbet of the crane marked W Y, is cast in one piece; it has a collar at *c*, which fits upon a pivot formed at the upper end of the column X. At the lower part of the gib is a collar which embraces the column near its base. On these two supports the gib turns freely round, so that its extremity W may be placed over either of the furnaces B B. The wheel work of the crane is supported in two frames *z z*, which are fixed to the gib by three bolts; it consists of a cog wheel *c* upon the end of the barrel, on which the chain winds; and a pinion *b*, which gives motion to the cog wheel. The axis of the pinion has a winch or handle, *a*, at each end, to turn it round. The chain *d*, from the barrel, is carried up over the pulley at *c*, which is fitted in a part of the gib immediately over the pivot at the top of the column X. The chain then passes over the pulley W, at the end of the gib, and has the tongs V T suspended to it. These are adapted to take up the pot between the hooks or claws T, at the lower ends. The two limbs are united by a joint like shears, and the upper ends V are connected with a great chain by a few links. The pot has a projecting rim round the edge, and the tongs take this rim to lift the pot out of the furnace. The pot being wound round to the required height by turning the handle *a*, the gib of the crane is swung round, to bring the pot over the pouring machine, and it is lowered down into it, for the convenience of swinging the crane round a worm which is fixed upon the column X at O, and a worm or endless screw is mounted in the frame *z*, to work in the teeth of the wheel. The screw, being turned by a winch on the end of its spindle, will cause the gib to move round on the column.

Fig. 3 of the engraving represents that part of the pouring machine in which the pot is placed; *m* is an axis, which is mounted in the frame of fig. 1, by the pivots at its ends. To this axis is fixed a cradle, which receives the pot. The cradle is joined together so as to open and shut, and the screw *m* draws the parts together until they fit. To the pot *a* there is fixed an arched rack L, forming a continuation of the principal bars of the cradle. When the cradle is in its place, as in fig. 1, the rack L is engaged by a pinion K, and can thereby be elevated to pour out the metal at a lip or spout, which is made at the edge of the pot for the purpose. The axis of the pinion K is turned by means of the winch D, with a train of wheels, D, E; F, G; I, H; and K. The man who turns this winch stands before the pot, so as to see what he is doing. The frame of the pouring machine is sufficiently evident from the figure. It is so made as to leave an open space beneath for the carriage, fig. 5, containing the ingot moulds.

Fig. 4, is a separate view of a pair of ingot moulds, the two parts, R and S, put together and form a complete mould, as shewn in fig. 5. The upper edge of the mouth is a little enlarged, to facilitate the pouring of the metal. The moulds are made of cast-iron. The part R has the bottom

side formed on it, and the other half, S, has one med on it. Before the moulds are used, they are an iron closet, which has flues surrounding it, and then rubbed on the inside with linseed oil.

fig. 1, is the carriage into which a row of these moulds l, as shewn at 4, and they are screwed up close by two p, so as to hold them tight; the moulds rest upon a hich is suspended by screws q, at each end, and can means be raised or lowered to suit different heights ds. The carriage is supported on four wheels Q Q, am upon a railway. P P is a rack fixed to the bot- tole of the carriage; in this rack, a cog-wheel N acts; wheel is turned by a pinion, which has a handle or , fixed upon it; by turning the handle, the carriage is along the railway: and any one of the moulds, fig. 4 i be brought under the spout of the pot, fig. 3; then g the handle D, fig. 1, the pot can be inclined so as to metal into the mould until it is full.

silver melting-house there are eight melting furnaces, es, and two pouring machines. Each crane stands in re of four furnaces, freely commanding the centre of d conveys the pots to the pouring machine. The eight are worked three times daily, and each pot contains, a average, 420 lbs. troy, making the total melting s. There are four men to each four furnaces; each or their own pots, and the whole meltings are finished, time of first charging in the morning, in little more hours. The whole of the silver meltings are conducted e superintendence of the surveyor of the meltings; and s no silver to be delivered to the company of money- e melter, unless he has a written order from the king's aster, authorizing such delivery.

eltings are performed by contract with the master of , and his first clerk, as melter. He is responsible to or for all the bullion he receives, and delivers weight ht, which renders his situation one of considerable great responsibility. He also finds security for the orformance of the duties of his office. The bars of silver, proved standard, are delivered over to the moneyers, form the various processes of the coinage under con- th the master of the mint, always delivering weight for They also give security for the due performance of as of their office.

Rollers employed at the Royal Mint.—The first to which the silver bars issued from the silver melting out of the royal mint, is subjected, is that of flattening, or laminating in the rolling mill. The bars, before they through the rollers, are heated to redness, which makes ch easier rolled. They are heated in a reverberatory

When the gold bars are subjected to the same pro- y are rolled cold, and a bar of an inch thick can be to the thickness of a half-sovereign, without ever being l, and could be reduced much thinner if necessary, shew the least symptom of cracking.

rawing (see the plate, fig. 6.) is an elevation of one ollers, and the wheel-work for giving motion to them. upper and B the lower roller; C C are the standards ast-iron frame which supports them. Each of these ls has an opening in it to receive the bearing brasses ivots of the rollers. The upper roller is suspended in hich are regulated by the large screws F, F, which f placing the rollers at a greater or less distance . This is shewn by the separate figure of one of the A A are the brasses, and k the hole to receive the pivot roller. On the upper part of the screw a collar f is ad from this two bolts g g descend, and are fastened asses A A, with nuts beneath. By these the roller is ed, but by turning the screw round, the brasses rise or : brasses A A are fitted very accurately into the grooves s into the standard C C. For the convenience of both screws round together, each has a cog-wheel F the upper end of it. These are turned by two worms H H, ed on a common axis, which has a handle G in front: by this handle the upper roller is either raised or lower- required, but will always be parallel to the lower one. standards C C are firmly bolted down to the ground.

sills D D, which are of cast-iron, and are bedded in the masonry E E. The standards are farther united by bolts a. At the upper part is a cross bar, fixed between the standards, to support a small table or platform, on which the metal is placed when it is to be presented to the rollers. The rollers are put in motion by a steam-engine. The crank of the engine has a cog-wheel upon it, which turns a pinion. Upon the axis of this is a very heavy fly-wheel, which turns with great velocity. On the end of the same axis is a pinion which turns a large wheel M, and this gives motion to a large shaft N N, which extends beneath the rollers, and is continued a sufficient distance in the same direction, to turn two pairs of rollers, one of which only is represented in the drawing. At L a wheel is fixed on this shaft, to turn the upper roller A, by means of a wheel K, which is supported in the standards k k, and its axis is connected with a short shaft r r, with the square on the end of the roller A; r r are the sockets by which the shafts are joined, and they admit of a little yielding when the roller is raised. The wheel O is fixed on the shaft N, to turn the lower roller B, by means of the wheel P; but the wheels P and O do not touch, being of smaller diameters, and an intermediate wheel is also applied on one side, so that its teeth engage with both the wheels O and P; by this means, the two rollers A and B are made to turn round in opposite directions, and then their adjacent surfaces will move together. The wheel P is supported in standards p p, and its axis R connected by a shaft Q, with the lower roller B. There is also a gauge to ascertain the thickness of the plates which are reduced by the operation of the rollers; it consists of two steel rulers fixed fast together at one end, and the other end is a certain distance asunder, forming an opening between them, which gradually diminishes to nothing: the sides of the rulers are divided. In using this gauge to determine the thickness of a piece of plate, the edge of the plate is applied to the opening between the rollers, and the divisions of the rollers shew the distance it will go into the opening before it fits tight; and the thickness is ascertained by the number of the divisions.

We now proceed to describe the machine by which the plates of metal from the rolling mill are cut into slips of a convenient width, for cutting out the circular pieces or blanks which are to form the coin. This width is generally that of two crowns, two half-crowns, and shillings.

Figs. 8 and 9, in the plate, are representations of the cutting machine. L L is a strong iron frame, which is screwed down to the ground-sills of the mill, so that the cog-wheel D will be immediately over the shaft which turns the rolling-mill, and can be turned by a cog-wheel upon that shaft. The cog-wheel D is fixed upon an horizontal axis B B, which is supported in the frame L L. A A is a similar axis placed at the top of the frame, and turned round by a cog-wheel C, which engages with the wheel D. On the extreme end of each axis A and B, a wheel or circular cutter E and F, is fixed. The edges of these cutters lie in close contact laterally, and overlap each other a little. The edges of the cutters are made of steel hardened, and they are turned very truly circular, and the edges which overlap are made very true and square. Whilst they are turning round, if the edge of any piece of metal be presented to them, it will be cut or divided just in the same manner as by a pair of shears. H is a narrow shelf, upon which the plate is supported when it is pushed forwards to be cut, and G is a guide fixed upon the shelf; the edge of the plate of metal is applied against this guide, whilst it is moved forward to the cutters. The guide is moveable, and the distance which it stands back from the cutting edges, or line of contact of the two cutters E F, determines the breadth of the slip of metal which will be cut off. Fig. 9 is another view of fig. 8.

To give these slips of metal the exact thickness which is requisite before they are cut up into blocks, they are subjected to a more delicate rolling; or they are drawn between dies by a machine, invented by Mr. Barton, the present comp- troller of the mint.

Figure 10 represents the finishing rollers, viewed at the end of the frame, in order to shew the manner of adjusting them; for it is only in those parts that they differ from the great rollers; a is one of the pivots or centres of the upper roller; and is accurately fitted in a collar of brasses, which collar

is held down in a cell at the top of the standard by a cap *d*, with two bolts and nuts. These are not intended for the adjustment of the rollers, as in the former instance, but the lower roller is moved for this purpose. The pivot *b* of the lower roller is received in a brass bearing, which is moveable in the opening in the standard frame. The brass rests upon a wedge *c*, which is fitted in a cross mortise through the standard. By forcing the brass farther in the wedge of the lower roller, it will be moved nearer to the upper roller. The standard at the other end of the rollers is made in the same manner, and the wedges of both must be moved at the same time. To give them motion, a screw *f* is fitted into each wedge, and upon these screws are worm wheels *g*, which are both moved by worms cut upon an horizontal axis, that extends across from one end of the frame to the other, and has a handle at the end to turn it round by, and move the screws and wedges both in equal quantity; *l* is the table on which the metal is laid to present it to the rollers.

The following engravings are descriptive of a new machine, invented by Mr. Barton, and employed at the royal mint for drawing the slips of metal between dies, by which a greater degree of accuracy and uniformity is obtained in the thickness of the metal. The operation is similar to wire-drawing.

The 11th, 12th, and 13th figures, represent a small machine for thinning the ends of the slips of metal, so that they will enter into the dies through which the whole of the slip is to be drawn. It is a small pair of rollers, which are shewn on a large scale in fig. 11. *A* is the upper roller, and *B* the lower; this has three flat sides, as represented; *C* is the slip of metal put between the rollers; *D* is a stop, adjustable in the line of the motion of the slip of metal *C*. The twelfth figure is an end view, and the 13th a side view, of the frame or machine in which the rollers are mounted. *A*, *B* are the rollers, which are made to turn together by pinions *a*, *b*. *F* is a large cog-wheel, which is fixed on the end of the axis of the lower roller. This cog-wheel is turned by a pinion *G*, which is fixed on an axis extending across the machine, and having a fly-wheel fixed on one end, and at the other a drum *H*, to receive an endless strap, by which the machine is put in motion; a crank is formed on the middle of this axis, and a rod *d*, is joined to the crank, to connect it with the moving blade *K* of a pair of shears, of which the other blade *L* is fixed to the frame. The distance of the rollers is regulated by a screw *e*, at the top of each standard. These screws have pinions at the top of them, and are turned round by a pinion, which is placed between them, and engages the teeth of both pinions, so as to give motion to the two screws at the same time, when the middle wheel is turned round by a cross handle, which is fixed to the top of it. If the slips of metal which are to be put into this machine are not exactly square at the ends, they are cut off smooth and square by the shears, which keep constantly moving; the end of the slip is then presented between the rollers, not on that side which would draw them in between the rollers, as in common rolling, but on the opposite side; when one of the flat sides of the lower roller comes opposite the upper roller, then the piece of metal can be pushed forwards between the two, until the end stops against the stop *D*, as in fig. 11; then as the rollers turn round, and the flat side of the lower roller passes by, the cylindrical parts of the roller will take the metal between, and roll it thinner at the end which is between the stops and the point of contact of the rollers.

Figs. 14 and 15. Fig. 14 is a section, to shew how the slip of metal *C* is drawn between the dies by the tongs, of which fig. 15 is a sort of ground plan. The dies are two steel cylinders made very hard, and extremely true; fitted into two sliders *D*, *D*, and held fast by clamp pieces screwed against them. The cylinders are accurately fitted into their beds in the slides, so that the steel shall be firmly supported, and prevented from bending or turning round, and to present but a small portion of their circumference against the slip of metal. The sliders *D*, *D* are fitted into a box, figs. 14 and 16; they fit flat on the bottom of the box, and two clamps *F*, *F* are screwed against the sliders, to confine them to the box. The lower slider is supported by two screws, *f*, *f*, and the upper side is forced down by a large screw *G*; this has a cog-wheel fixed on the top of it, with a pinion and lever to turn the screws round very slowly, and

regulate the distance between the dies. *H* is a clamping nut, fitted upon the screw, to take off all possibility of shake; the sliders also are bound fast sideways by screws tapped through the sides of the box, the points of which press upon steel plates between them and the sliders. In order to render the contact between the points of the screws supporting the under side, and the point of the adjusting screw, forcing the upper slider, still more complete, two extending screws are introduced at the ends of the steel dies between the sliders, by which a sufficient degree of contact to overcome the spring of the materials may be excited, before the dies come into action on the slip of the metal, fig. 15.

Rolling Machine. The box of dies, fig. 17, is fixed at one end of a long frame. This frame supports two axes *A*, *A*, one at each end. Upon these axes wheels are fixed, to receive endless chains *B*, *B*, which move along a sort of trough or railway, formed on the top of the frame. The chains are kept in motion by a cog-wheel *C*, which is fixed upon the axis most remote from the box of dies. This cog-wheel is turned by a pinion *D*, on the axis of which is a wheel *E*; and this wheel is turned by a pinion *F* on the axis of the drum *G*, which is moved by an endless band, proceeding from some of the wheels in the mill, and which is thrown in and out of gear at pleasure by a tightening roller. The slip of metal is drawn through the dies by the chain, with a pair of tongs.

Figs. 14 and 15—*a* *b* are the two jaws of the tongs, which are united with each other by the joint pin *c*. This has fitted on each, a small roller or wheel, which runs upon the railway or top of the frame; *d* *d*, fig. 15, are a similar pair of wheels, the axle of which is connected with two links *e* *e*; this axle passes between the tails of the tongs, but is not fixed to them. The ends of the links have a double hook formed on them, as shewn at fig. 15. The tongs run upon their wheels immediately over the endless chain, so that when the end of the links *e* *e* is pressed down, one of the hooks catches on a cross pin of the chain, as in fig. 15; the axle of the wheel *d* *d* acting between the inclined parts of the tails of the tongs, tends to throw them asunder, and, at the same time, the jaws of the tongs bite with very great force; the links *e* *e* draw the tongs along with the chain *B*, *B*. The links are carried a long way beyond the axle of the wheels, and have a sufficient weight *h* fastened to them, which will lift up the hooked end *f*, and disengage it from the chain, except when there is a considerable strain on the tongs.

To use this machine, a boy takes hold of the tongs by the handle *r*, when they are disengaged from the chain, and pushes the tongs forward to the box of dies. The tongs run freely upon their wheels, and the jaws open when moved in that direction, because two small pins *i*, *i*, are fixed between the links, and acting on the outsides of the tails of the tongs, close them together, and this at the same time opens the jaws. The tongs are pushed up close to the box of dies, and the jaws enter into a recess *N*, fig. 14, which is formed for that purpose. Another boy takes a slip of metal, which is previously made thin by the rollers, fig. 11, and introduces it between the dies, and also between the jaws of the tongs, which are open. The boy who holds the tongs now takes the handle *s*, which is fixed on the back of the tongs, and holds it fast, whilst with the other hand he draws the handle *r*, at the end of the links, away from the tongs. This has the effect of closing the jaws of the tongs upon the slip of metal between them; at the same time the boy depresses the handle *r*, and the hook at the end of the links *e* *e* will be caught by the first cross-pin of the chain which comes beneath them. This puts the tongs in motion; but the first action is to close the jaws, and bite the piece of metal with great force, in consequence of the axletree of the wheels being placed between the inclined planes of the tongs. When the tongs have closed on the metal with all their force, they move with the chain, and draw the slips of metal through the dies, which, operating upon the thicker part of the slip with greater effect than upon the thin, reduces the whole to an equable thickness. When the whole is drawn through, the strain upon the tongs is gradually released; and the weight lifting up the hook at the other end of the links, they are ready to be advanced again to the die, to draw another bar. The frame, of which we have given a drawing, contains two pair of dies, and the same wheel serves for both. At the mint there are two

Process of Coining at the Royal Mint.

P. II.

machines of this description; they are placed side by side, with a sufficient space for the boys to work between them. These machines were made by Mr. Maudsley, under the direction of the inventor. The slips of metal produced from this machine are considerably more uniform in thickness than when finished at the adjusting rollers; consequently, the individual pieces are made more nearly to the standard weight, which was the object in view by this invention. This has become a point of great importance in the practice of the mint, from the remedy on gold in weight being reduced from 40 to 12 troy grains. When the pieces cut from slips of metal, prepared from the drawing machine, are pounded and weighed, which is telling the number of pieces in a pound troy, sovereigns or half sovereigns, the variations from standard either way seldom exceed three grains troy. It is reckoned good work from the adjusting rollers when the variations are under six troy grains.

Adjusting. The blanks, after being cut out by Bolton's cutting-out press, are carried to the sizing room, where each individual piece is adjusted to its standard weight. The light pieces are selected for remelting, and the heavy ones, if not considerably beyond weight, are reduced to their standard weight by rasping their surfaces with a coarse rasp or file. The superior accuracy of Mr. Barton's beautiful machine (described above) has considerably abridged the labour of this inelegant and unmechanical process. The pieces thus adjusted are in a state of great hardness, from compression by the rolling and drawing processes, and by which, in fact, their latent heat has been squeezed out. They attain their softness again by being heated to a cherry red heat in a reverberatory furnace; after which they are boiled in a very weak sulphuric acid, which makes them very clean, and of a very white colour. When dried, either in warm sawdust, or over a very slow fire, they are in a state for the two next processes, which are the milling, and the coining or stamping.

Milling. Plate II. The operation of milling is to be performed round the edge, to prevent their being clipped or filed, which was a fraud commonly practised upon the ancient money made before the introduction of milling or lettering round the edge. The construction of the milling machine will be easily understood, from the inspection of figs. 1 and 2, being an elevation and plan of the same. The parts which operate upon the piece of money, consist of two steel bars or rulers D D, the adjacent edges of which are cut or fluted; the lower bar, seen in plan fig. 2, is immoveable, being fastened down by two clamps to a cast-iron plate D, forming the base of the whole machine; the upper bar is prevented from rising by the two vertical pieces, but has the liberty of moving backwards and forwards in the direction of its length, and is guided in such motion by laying half its thickness in a groove formed in the plate D. A rack, C C, fig. 1, is fixed to the moving ruler, which engages in the teeth of the wheel B, mounted on an axis lying across at right angles to the ruler, and supported at its ends by two standards rising up from the plate D. On one end of the axis a handle is fixed for giving motion to the machine. Two blanks are put into the machine at the same time, as seen in the second figure, and the lower ruler can be made to approach nearer to, or recede farther from, the upper ruler, by the two screws f f, to take in a different sized piece between them. The operation of the machine is very simple. Two blanks being placed between the edges of the rulers, the handle A is turned round half a turn, which moves the upper ruler endways, sufficient to mark the blank all round the edge. The two milled pieces are then taken out, and two other blanks are placed between the rulers; the handle A being turned half round in an opposite direction, carries the upper ruler back again to the position in which it first stood; thus two more blanks are milled, and so on. The machine is placed upon a strong wooden bench, to raise it to a convenient height for the man who turns the handle; the blanks are placed in the machine by a boy, near to that where the handle is.

The 3d and 4th figures on Plate II. are further illustrations of Bolton's cutting-out press. Fig. 3 shows the manner of the horizontal wheel acting on the roller F. It represents a horizontal plan of the upper part of the axis. S, fig. 3, is part of the rim of the large wheel, and T, one of the projecting cogs, which, when the wheel turns in the direction of the arrow, will

take the roller F, at the end of the lever F D, and turn the lever round in that direction which will wind up the screw, and raise the punch out of the die. This action also draws a rod H, which is connected with the lever by a joint; the other end is connected with a bended lever, from the other end of which a rod descends, and has a piston fixed to it. Fig. 4 is the catch. At K it is moveable on a joint E, and is thrown upward by a spring k. To this spring a cord O is fastened, and the lower end of the cord has a treadle fastened to it. For a perspective view of Barton's Rolling Machine, see the plate.

Coining Press.—We now proceed to give a description of the Coining Press, an elevation of which is exhibited in fig. 6, in the Plate. C C C is a strong cast-iron frame, screwed down on a stone basement; the upper part is perforated perpendicularly, to receive the screw, D. One of the steel dies which strike the coin, is fixed to the lower end of this screw by a box, fig. 6, and the other die is fixed in a box, fig. 7, which is fastened down upon the base of the press. The heavy balance weights, R R, fig. 5, are fixed on the top of the screw, which, being turned round, press the upper die down upon the blank piece of coin, which is laid upon the lower die, and gives the impression; a sufficient force being obtained from the momentum of the loaded arms, R R. The motion is communicated to the screw by a piece, A, which ascends to the ceiling of the coining-room, and is worked by a steam-engine, with machinery, in the apartment in the room over the coining-room.

Eight presses, similar to this, are placed in a row upon the stone basement, and very strong oak pillars are erected upon the basement, and reach to the ceiling. Each press is contained between four such pillars, and iron braces are fixed horizontally from one pillar to another on the opposite side. These braces support blocks of wood, against which the ends, R R, of the arms strike, to stop them from moving farther than necessary, as, without such precaution, the hard steel dies would sometimes come in contact, and be broken. The piece of blank coin is contained within a steel ring or collar, whilst it is stamped, and this preserves its circular figure. The ring is shewn at a large size at W, fig. 9. V, fig. 8, is a three-pronged spring, which always bears the spring upwards; the opening through the ring, W, is made to fit upon the neck of the lower die, T, fig. 7. When the ring is dropped upon the neck of the die, the upper surface of the ring and of the die will be in one plane. The ring admits of being raised up upon the neck, and will then form a recess or cell, which is just adapted to receive a piece of money. The collar, W, is made to rise and fall upon the neck of the die by means of the levers, G G, fig. 8; these are fitted upon centre-pins or joints, in a large ring, g g, which is placed on the outside of the box, fig. 7, containing the lower die, T, and is fixed fast upon it, as shewn in fig. 5, by clamping the screws, g g. The levers, G G, are forked at the outer ends, to admit studs at the lower ends of iron rods, E E, which rise up through holes in the solid metal of the press, and are united to a collar, G, fitted on the upper part of the screw, D. When the screw of the press is turned back, and the upper die is raised up, the rods raise the outside ends of the short levers, G, and the inside depresses the ring; a blank piece of money is laid upon the die, and when the screw is turned to bring the upper die down upon it, ready to stamp the impression, the levers, G, are released, and the triple spring, V, lifts the collar up, so that it surrounds the piece of money; and in this state the blow is struck. Immediately after, the press returns by its recoil, and then the levers, G, force the collar down upon the neck of the die, and leave the piece free. The lower die is fixed in a box, fig. 7, by the screws, t t, which admit of adjusting it with precision beneath the upper die. The box, fig. 7, is screwed down upon the base of the press by four screws. The upper die is shewn at S, fig. 6, which explains how it is fastened to the screw; s s are four screws, by which the die is held in a box, fig. 6. The box is fitted into a ring or collar, as shewn by the dotted lines, F; see also fig. 6. The arms of the collar, F, are attached to the rods, E E, by two nuts at each end; and this makes the collar, F, and the box, fig. 11, always follow the screw, and keep in close contact with the end of the screw, which enters into a cell on the top of the box, fig. 6, but leaves the screw at liberty to turn round independently of the box.

Fig. 2, is a ring, which is fastened by its screws, w w, to the

screw of the press, a claw *Z* descends from the ring, and enters into the cavity *a* in the size of the coin, fig. 6, which cavity is made three times as wide as the claw, *Y*, and therefore, when the screw is turned round for a certain distance without turning the die, fig. 6, but beyond the limits of this motion the screw and the die are drawn together. The intention of this is to press the upper die down upon the coin with a strong pressure, and to draw the die away to rise up with a similar motion. When the screw is turned round, the die impression on the coin remains, and the die is drawn up as to allow the screw to return, and draw the die from immediate contact with the coin, before the coin begins to turn round with the same motion as the screw.

Fig. 7 is a section of the screw over the box for the upper die, and is a kind of wedge to keep the upper die firm in its seat. The screw of the press is made cylindrical at the upper and lower ends, as represented in fig. 8, and their ends are secured by a kind of collar, which are locked tight by screws. The screw of the press is partly concealed within the solid metal frame, and has a collar which turns to force the die down, the pressure being effected by the collars.

It will be necessary to show how the Coining Press is made to strike a large piece of money which it strikes, and to feed it out as it is struck.

H I K, fig. 9, is a lever of which *L* is the fulcrum; it is supported at *H*, and is turned round by the cheek of the press, and is acted upon by a screw. The upper end of the lever is actuated by a screw, which is fixed upon the screw, *D*. When the screw is turned round, the pressure in the sector being of a spiral nature, it moves the end, *H*, of the lever, to and from the screw, and the lower end, *K*, of the lever being longer, it moves a considerable distance to and from the centre of the press. A collar or groove in a piece of metal is fixed to the perpendicular bar, *Q*, and the upper end of the lever, *H*, is raised in a groove to prevent any lateral deviation.

The lever *K* gives motion to a slider, *L*, fig. 20, which is supported in a socket, *O*, screwed against the inside cheek of the press, and the slider, *L*, is directed exactly to the centre of the press, and on the lever of the upper surface of the die.

Figures 19 and 20, represent four views of the slider and socket. *N M O*, fig. 19, is a kind of trough or socket in which the slider runs; this slider is formed of two pieces hollowed out on the sides, which are put together, and the two pieces are held together by screws. *O* is the part by which the socket is fastened to the press. The slider is a thin steel plate, *p*; and this is made in two pieces, *P* and *p*, which are united by the joint *q*, fig. 15. The extreme end is made with a circular cavity; and when the two limbs shut together, they will grasp a piece of money between them, and hold it by the edge; but if the limbs are separated, the piece will drop out. The limb, *p*, of the slider, is opened or shut by the same movement which moves the slider endways in its socket. Thus a plate, *L*, is applied flat beneath the socket, *M N*, and has an edge turning up and applying to the upright edge of the socket. A pin is fixed into this edge, and is embraced by the fork at the lower end of the lever, *K*, fig. 5. By this means the sliding piece, *L*, is made to move on the outside of the socket, *N*. It is kept in its place by a fillet, *k*, fig. 14, which is screwed to the upright edge of *L*, and the fillet enters a groove formed along the upper surface of the socket, *N*.

The sliding piece, *L*, is made to move the steel slider within the socket by means of three studs, which project upwards from the bottom plate of *L*, fig. 16, at *r r s*, and pass through grooves in the bottom plate of the slider, so as to act upon the steel slider, *P*, in the manner shewn in fig. 15. The left-hand piece, *r*, is received into an opening in the middle of the slider, *P*, fig. 15. The other two studs, *r* and *s*, fig. 16, include the shank of the limb, *p*, between them, and these studs are cut inclined, so that, when the piece, *L*, is moved to the right, the studs, *r s*, will close the limb, *p*, until they are shut, and then the studs will carry the slider forward; but, if the sliding piece, *L*, is moved to the left, its studs will first close the limbs, and will then draw back the slider on the top of the socket, *N*; a tube, *M*, is placed, figs. 19 and 20, and it is filled with blank pieces of coin; the tube is open at bottom to the slider, and the pieces rest upon it. When the screw of the press is screwed down

the slider, *P*, draws back to its farthest extent, and the circle formed at the end between its limbs comes exactly beneath the tube, *M*; the limbs being open, a blank piece of coin drops down into the circle of the slider; then the screw of the press, in returning, moves the lever, *H I K*, and the piece, *L*; this acts by its studs upon the moveable limb, *p*, and closes it upon the blank piece, the studs having now found a reaction, push the slider, *P*, forward in its socket, and carry the piece forward upon the die, as shewn in fig. 13, and which will push off the piece last struck. The screw having now arrived at its highest position, begins to descend, and the slider, *L*, to return; but the first action of the studs of the sliding piece, *L*, is to open the limb, *p*, and then the slider withdraws, leaving the piece of money placed upon the die. As the screw of the press descends, the ring, *W*, rises up to enclose the piece, as before mentioned, whilst it receives the stroke, and the slider, *P*, at the same time returns to take another piece from the tube, *M*, in the same manner as before described.

Fig. 13, is a section, to shew the manner of mounting the lower die for a coining press. This is used in the French Mint. *V* is a piece of metal or box, as it is placed upon the base of the press, and held down by a ring with screws, *t*; this holds it fast, but admits of lateral adjustment. In the top of the box is a hemispherical cavity to receive the hemisphere, *W*; the upper side is flat, and the die, *T*, is placed upon it, to hold the die down; it has a small projecting rim at the lower edge, and a rim, *X*, is screwed upon the outer edge of the box, *V*, to hold the die down. The object of this plan is, that the die may always bear fairly to the money which it is to strike.

Figures 17 and 18, represent a divided collar, invented by Mr. Droz, for striking money with the letters round the edge. *X*, fig. 18, is a very strong piece of iron, which has a circular opening through the centre; into this, six segments, *w, w*, are fitted, and between them they leave an opening, *W*, the size of the piece of money; the interior edges of these segments are engraved with the pattern or device which it is required to impress upon the edge of the piece. The segments are fitted in the piece, *X*, by centre pins, upon one of which pins each segment can rise in the manner of a centre.

The intention of this is to have a piece of money placed on the die within the space, *W*; then, when the pressure is made upon the piece, the die descends some space, and by this motion the segments close together around the edge-piece, and imprint upon the edge of it. When all the segments come into one plane, the die arrives at the firm seat, and the metal receives the stroke which makes the impressions on its surfaces. The die is suspended in a sort of cup, which rises and falls with the screw, nearly the same as the collar, *F*, in fig. 13. The money, when struck, is passed through tubes of the diameter of the different species, which readily detects any pieces which may have been improperly struck.

Mr. Bolton's Cutting-out Press employed at the Royal Mint.—In the process of coining followed at the Royal Mint, plates of metal are cut out into circular pieces, nearly of the size of the intended coin, by a machine invented by Mr. Matthew Bolton, and for which he obtained a patent in 1790. A drawing of it is exhibited in fig. 12, where *CCC* is a cast-iron frame, that is fixed on a stone basement. *E* is a screw, which is fitted through the top of the frame, and actuates a slider *F*. At the lower end of the slider a steel punch *a* is fixed, the diameter of which is equal to that of the pieces which are to be cut out; *c* is the steel die, which has a hole in it of a proper size to fit the steel punch; *d* is a box, with screws for adjusting the die, so that the hole in it will be exactly beneath the punch. The slider *F* is fitted into a socket *G*, which guides it, so that it descends exactly into the hole in the die. *e* is a piece of iron fixed at a small distance above the die *c*, and with a hole through it to admit the punch; the design of this piece is to hold down the piece of metal when the punch rises, otherwise the piece would stick to the punch. On the upper end of the screw a piece *Q* is fixed, from which an arm projects, with a weight *P* at the end; it is this weight which gives the necessary momentum to punch out the piece. *D* is a spindle fixed upon the piece *Q*, in the line of the screw, and supported in a collar *A* at the upper end; above this collar a lever *D G F* is fixed, at one extremity of which there is a roller *F*, that is

acted upon by the projecting teeth of a large horizontal wheel, turned round by the power of a mill. When the wheel turns it catches the roller F, which turns the lever round, and thereby winds up the screw, and raises the punch out of the die. The same action draws a rod H, which is connected with the lever by a joint: the other end of this rod is connected with a bended lever, from the other arm of which a rod descends, and has a piston fixed to it. This piston is fitted into a close cylinder; hence, when the piston is drawn up, it makes a vacuum in the cylinder, and the pressure of the atmosphere on the piston causes a reaction: and the instant that the roller F escapes or slips off from the tooth of the wheel, the reaction of the piston draws the joint H back, and makes the screw turn round in that direction, which causes the punch to descend and cut out a piece from a plate of silver or gold laid upon the die. When the machine requires to be stopped, there is a catch, which is suffered to rise up and hook the lever G. The catch is thrown up by a spring, to which a cord, with a treadle, is fastened. A boy who applies the plates of metal to this machine, places his foot on the treadle, draws down the spring and catch, and then the machine makes a cut every time that a cog of the great wheel passes by; but if the boy relieves the treadle, then the spring lifts up the catch; and when the end of the lever G comes over the catch, it will be caught thereby, and held fast from returning by the action of the exhausted cylinder. R is a strong wooden spring, against which the balance-weight P strikes to stop its motion when it has made its required stroke to pierce the plate. Twelve of these cutting-out presses are to be seen at the Royal Mint, arranged in a circle round a great wheel, which is turned by a steam-engine, and has a large fly-wheel fixed on the same axis, just above the wheel, to regulate the motion. The stone basement on which the presses are fixed is circular, and the bearings A are all fixed in a circular iron frame, erected on an iron column placed between each press. The whole forms a very handsome colonnade, and is placed in the centre of a circular room, which is lighted by a sky-light in the dome. The air cylinders are placed within hollow pilasters, which ornament the walls of the room, and appear to support the dome. The whole presents as elegant an arrangement of machinery as can well be conceived.

MINT. See **MENTHA**.

MINUTE, the sixtieth part of a degree; or, in time, the sixtieth part of an hour. These are both denoted by a small dash, as ' placed over the number of them; though, to prevent confusion, it is better to mark the latter by a small *m*.

MIRA, a singular star in the neck of Cetus, discovered in 1506, and marked in the British catalogue as a star of the third magnitude, appears and disappears periodically seven times in six years, continuing in the greatest lustre for fifteen days together. During 334 days, it continually shines with its greatest light, appearing as a star of the third magnitude; then it diminishes till it entirely disappears for some time from the naked eye. In fact, during that period it passes through its several degrees of magnitude, both increasing and diminishing.

MIRACLE, in its original sense, is a word of the same import with wonder; but in its usual and more appropriate signification, it denotes "an effect contrary to the established constitution and course of things, or a sensible deviation from the known laws of nature." The history of almost every religion abounds with relations of prodigies and wonders, and of the intercourse of men with the gods; but we know of no religious system, those of the Jews and Christians excepted, which appealed to miracles as the sole evidence of its truth and divinity. The pretended miracles mentioned by pagan historians and poets are not said to have been publicly wrought, to enforce the truth of a new religion, contrary to the reigning idolatry. Many of them may be clearly shewn to have been merely natural events. See **MAGIC**. Others of them are represented as having been performed in secret on the most trivial occasions, and in obscure and fabulous ages, long prior to the era of the writers by whom they are recorded. And such of them as at first view appear to be best attested, are evidently tricks contrived for interested purposes; to flatter power, or to promote the prevailing superstitions. For these reasons, as well as on account of the immoral character of the divinities by whom they are said to have been wrought, they are

altogether unworthy of examination, and carry in the very nature of them the completest proofs of falsehood and imposture.

MIRAGE, a name given by the French sailors to an optical phenomenon, on which M. Monge read his memoir to the Institute at Cairo, during the French invasion of Egypt. It often happens at sea, that a ship seen at a distance appears as if painted in the sky, and not to be supported by water. A similar effect was observed by the French in the course of their march through the Desert. The villages seen at a distance, seemed to be built on an island in the middle of a lake. In proportion as they approached, the apparent surface of the water became narrower, and ultimately disappeared entirely; while the same illusion was repeated on a village at a little farther distance. This phenomenon has been variously accounted for by different philosophers. Monge ascribes the effects to a diminution of density in the lower stratum of the atmosphere. This, in the Desert, is produced by the increase of heat, arising from those communicated by the rays of the sun to the sand with which this stratum is in immediate contact. At sea, it takes place where, by particular circumstances, such as the action of the wind, the lower stratum of the atmosphere holds in solution a greater quantity of water than the other strata. In this state of things, the rays of light which come from the lower part of the heavens, having arrived at the surface that separates the less dense stratum from those above it, do not pass through that stratum, but are reflected, and paint in the eye of the observer an image of the heavens; which appearing to him to be below the horizon, he takes it for water when the phenomenon occurs on land. And if at sea, he thinks he sees in the heavens all those objects which float on that part of the surface occupied by the image of the heavens.

MIRROR, in Catoptrics, any polished body impervious to the rays of light, and which reflects them equally. Mirrors were anciently made of metal; but, at present, they are generally smooth plates of glass, tinned or quicksilvered on the back part, and called looking-glasses. Mirrors are either plane, convex, or concave. The first sort reflects the rays of light in the direction exactly similar to that in which they fall upon it, and therefore represents bodies of their natural magnitude. But the convex ones make the rays diverging much more than before reflection, and therefore greatly diminish the images of those objects which they exhibit: while the concave ones, by collecting the rays into a focus, not only magnify the objects they shew, but will also burn very fiercely when exposed to the rays of the sun; and hence they are commonly known by the name of burning mirrors. Some of the more remarkable laws and phenomena of plane mirrors are as follows:—1. A spectator will see his image of the same size, and erect, but reversed as to right and left, and as far beyond the speculum as he is before it. As he moves to or from the speculum, his image will, at the same time, move towards or from the speculum, also on the other side. In like manner, if, while the spectator is at rest, an object be in motion, its image behind the speculum will be seen to move at the same rate. Also when the spectator moves, the images of objects that are at rest will appear to approach or recede from him, after the same manner as when he moves towards real objects. 2. If several mirrors, or several fragments or pieces of mirrors, be all disposed in the same plane, they will only exhibit an object once. 3. If two plane mirrors, or speculums, meet in any angle, the eye, placed within that angle, will see the image of an object placed within the same, as often repeated as there may be perpendiculars drawn determining the places of the images, and terminated without the angles. See **OPTICS**.

MISCHIEF, in Law. Malicious mischief is an injury of such a gross nature to personal property, that although it is not done with a felonious intention, or an intent to steal, the law has inflicted punishment upon it by various statutes. Of these, are statutes against destroying dikes and bridges in the fens of Norfolk, &c.; setting fire to stacks of corn, &c., and imprisoning persons on the borders for the purpose of obtaining ransom; killing cattle, maiming sheep, &c., a trespass punishable with treble damages. Captains and mariners setting fire to ships is felony, and also making a hole in a ship in distress, &c., is felony, and death by statute 12 Anne, s. 12,

c. 18. Wilfully and maliciously tearing, cutting, spoiling, or defacing the garments of any person in the streets or highways, or assaulting, with intent to do so, is felony. There are acts which relate to the prevention of setting fire to out-houses with corn, damaging fishponds, trees planted in gardens, cutting down sea-banks, hop-binds, setting fire to mines, preventing persons from buying corn, setting fire to gorse, furze, &c.; wilfully burning engines in mines, fences, enclosures, breaking into houses of the plate glass company, with intent to destroy utensils; breaking into houses to cut or destroy cloth, serge, linen, &c., in the loom, and other similar offences.

MISCHNA, or **MISNA**, the code or collection of the civil law of the Jews. The Jews pretend, that when God gave the written law to Moses, he gave him also another not written, which was preserved by tradition among the doctors of the synagogue, till rabbi Juda, surnamed the Holy, seeing the danger they were in, through their dispersion, or departing from the tradition of their fathers, reduced them to writing. The Misna is divided into six parts: the first relates to the distinction of seeds in a field, to trees, fruits, tithes, &c. The second regulates the manner of observing festivals; the third treats of women and matrimonial cases; the fourth of losses in trade, &c.; the fifth is on oblations, sacrifices, &c.; and the sixth treats of the several sorts of purification.

MISDEMEANOUR, in Law, signifies a crime. Every crime is a misdemeanour; yet the law has made a distinction between crimes of a higher and a lower nature; the latter being denominated misdemeanours, and the former felonies, &c. For the understanding which distinction, we shall give the following definition from Blackstone's Commentaries, vol. iv. p. 5. "A crime, or misdemeanour, is an act committed or omitted, in violation of a public law, either forbidding or commanding it. This general definition comprehends both crimes and misdemeanours; which, properly speaking, are mere synonymous terms; though, in common usage, the word crime is made to denote such offences as are of a deeper and more atrocious dye; while smaller faults and omissions of less consequence, are comprised under the gentler name of misdemeanours only."

MISE, in Law books, is used in various senses. Thus it sometimes signifies costs or expenses, in which sense it is commonly used in entering of judgments in actions personal. It is also used for the issue to be tried on the grand assize; in which case, joining of the issue upon the mere right, is putting in issue between the tenant and demandant,—who has the best or clearest right.

MISERICORDIA, in Law, is an arbitrary fine imposed on any person for an offence. This is called misericordia, because the amercement ought to be but small, and less than that required by magna charta. If a person be outrageously amerced in a court that is not of record, the writ called *moderata misericordia*, lies for moderating the amercement according to the nature of the fault.

MISFEASANCE, in Law books, signifies a trespass.

MISFORTUNE, an unlucky accident.—Misfortune, or chance, in Law, a deficiency of the will; or committing an unlawful act by misfortune or chance, and not by design. In such case, the will observes a total neutrality, and does not co-operate with the deed; which therefore wants one main ingredient of a crime. See **CRIME**. Of this, when it affects the life of another, we have spoken under the article **HOMICIDE**; and in this place have only occasion to observe, that if any accidental mischief happen to follow from the performance of a lawful act, the party stands excused from all guilt; but if a man be doing any thing unlawful, and a consequence ensues which he did not foresee or intend, as the death of a man, or the like, his want of foresight shall be no excuse; for, being guilty of one offence, in doing antecedently what is in itself unlawful, he is criminally guilty of whatever consequence may follow the first misbehaviour.

MISNOMER, in Law, a misnaming or mistaking a person's name. The Christian name of a person should always be perfect; but the law is not so strict in regard to surnames, a small mistake in which will be dispensed with, to make good a contract, and support the act of the party. See **PLEA TO INDICTMENT**.

MISPRISION, a neglect, oversight, or contempt, applied chiefly to misprision of treason, which is a negligence in not revealing treason, or felony, to a magistrate, where a person knows it to be committed: it is also applied to great misdemeanours. It is, therefore, negative or positive, as it is an act or a concealment of crime. To avoid misprision of treason, the party must make full discovery to a magistrate. To counterfeit foreign coin, not current here, is misprision of treason. A misprision of felony may be by concealing it, or by taking back again a man's goods which have been stolen, which is now made felony. Concealing treasure trove falls under this head. In the class of positive misprisings, or high misdemeanours, are the mal-administration of high officers, and embezzling public money. Contempts against the king's authority, some of which incur a *præmunire*; contempts against the king's palace or courts. In the palace, if blood be drawn in a malicious assault, it is punishable by perpetual imprisonment, fine, and loss of the offender's right hand, 33 Henry VIII. c. 12. And striking, whether blood is drawn or not, in the king's superior courts, or at the assizes, is punishable with equal or greater severity. A rescue of a prisoner in such a court is punished with perpetual imprisonment, and forfeiture of goods, and the profit of lands during life. Of a less degree are reckoned also the injurious treatment of those who are under the immediate protection of a court of justice, the dissuading a witness from giving evidence, and the disclosing, by a grand jury, to the person indicted, of the evidence against him.

MISRECITAL, in deeds, is sometimes injurious, and sometimes not; if a thing be referred to time, place, and number, and that is mistaken, all is void.

MISSIONARIES, such ecclesiastics as are sent by any Christian church into pagan or infidel countries, to convert the natives, and establish the Christian religion among them. Custom, the tyrant of language, has applied this term in a sense very different from its original acceptation; for there may be missions political or commercial, as well as religious.

MISSIVE, something sent to another, as missive letters; meaning letters sent from one to another upon business, in contradistinction to letters of gallantry, points of learning, despatches, &c.

MITE, a small coin, formerly current, equal to about one-third of a farthing. It also denotes a small weight used by the moneyers. It is equal to the twentieth part of a grain, and divided into twenty-four doits.

MITRE, a sacerdotal ornament worn on the head by bishops, and certain abbots, on solemn occasions; being a sort of cap, pointed, and cleft at top. The high priest among the Jews wore a mitre or bonnet on his head. The inferior priests among the Jews had likewise their mitres. Those young women among the primitive Christians who professed a state of virginity, and were solemnly consecrated thereto, wore a purple and golden mitre as a badge of distinction. The pope has no less than four different mitres, which are more or less rich, according to the solemnities of the festivals on which they are worn. The cardinals anciently wore mitres; some canons of cathedrals have the privilege of wearing the mitre; and some great families in Germany bear it for their crest.

MITTIMUS, a writ by which records are transferred from one court to another. The precept directed to a gaoler, under the hand and seal of a justice of the peace, for the receiving and safe keeping a felon, or other offender, by him committed to gaol, is called a mittimus.

MIZZEN, the aftermost or hindmost of the fixed sails of a ship, extended sometimes by a gaff, and sometimes by a yard which crosses the mast obliquely, the fore end reaching almost down to the deck, and the after end being peaked up as high above the middle of the yard which is attached to the mast: the head and foreleech, or the mizzen, are laced upon the gaff (or yard) and mast, and the sheet hauls out near the taffrail.

MIZZEN Mast, the mast which supports all the after sails. The explanations of the rigging, yards, and sails of this mast being in general applicable also to the same furniture of both the other masts, the reader is referred to the articles **SHROUD**, **STAY**, **YARD**, &c. observing only that the epithet of *Fore*, *Main*, or *Mizzen*, is added to each term, to distinguish them from each other.

MNEMONICS, the art of improving the memory. It sufficiently appears that the principal expedient for assisting this useful faculty is derived from association, and of this Simonides and Cicero availed themselves in the early ages. All the abilities of the mind borrow from memory their beauty and perfection; without this, the other faculties of the soul are almost useless. To what purpose are all our labours in knowledge and wisdom, if we want memory to preserve and use what we have acquired? What avail all our intellectual or spiritual improvements, if they are lost as soon as they are obtained? Memory alone enriches the mind, by preserving what our labour and industry have collected. Without memory, there can be neither knowledge, nor arts, nor sciences. Without the assistance and influence of this power, mankind would experience no improvement in virtue, in morals, or in religion. The soul of man would be but a poor, destitute, naked being, without memory. If we except the fleeting ideas of the moment, it would present an everlasting blank.

It is often found, that a fine genius has but a feeble memory; for where the genius is bright, and the imagination vivid, the power of memory may be too much neglected, and lose its improvement. An active fancy readily wanders over a multitude of objects, and is continually entertaining it with new and transitory images. It runs through a number of new scenes, or new pages, with pleasure, but without due attention; and seldom suffers itself to dwell upon any of them long enough for the mind to receive a deep impression, or for the remembrance of the subject to be lasting.* Consequently, many persons of very bright parts, and active spirits, have but short and narrow powers of recollection; possessing riches of their own, they are not solicitous to borrow from the stores of others. When the memory has been almost constantly employed in making new acquisitions, and when there has not been a judgment sufficient to distinguish what was fit to be remembered, and what was idle, trifling, or needless, the mind has been filled with a wretched heap of words or ideas. In this case, the soul had large possessions, but no true riches. "Whatever," as Milton says, "old Time, with his huge drag net, has conveyed down to us, along the stream of ages; whether it be *shells or shell fish, jewels or pebbles, sticks or straws, sea weeds or mud*;" all is treasured up indiscriminately, by those persons who have not the judgment to determine what is to be remembered, and what is to be forgotten. How many excellent judgments and reasonings are framed in the mind of a wise and studious man, in a length of years! How many worthy and admirable notions has he possessed in life, both by his own reasonings, and by his prudent recollections in the course of his reading! But, alas! how many thousands of them vanish, and are lost for want of a happy and retentive memory.

Mr. Locke, speaking of the continual decay of our ideas, beautifully observes, "The ideas, as well as children of our youth, often die before us: and our minds represent those tombs to which we are approaching; where, though the brass and marble remain, yet the inscriptions are effaced by time, and the imagery moulders away. The pictures drawn in our minds are laid in fading colours, and, if not sometimes refreshed, vanish and disappear. How much the constitution of our bodies, and the make of our animal spirits, are concerned in this, and whether the temper of the brain makes this difference, that, in some it retains the characters drawn on it like marble, in others like free stone, and in others little better than sand; I shall not here inquire: though it may seem probable, that the constitution of the body does sometimes influence the memory; since we oftentimes find a disease quite strip the mind of all its ideas, and the flames of a fever, in a few days, calcine all those images to dust and confusion, which seemed to be as lasting as if graven in marble."

A good memory has these qualifications: (1.) It is ready to receive and admit, with perfect ease, the various ideas of words and things which are learned or taught. 2. It is copious enough to treasure up these ideas in great number and variety.

* In all these cases, (says Locke,) ideas in the mind quickly fade, and then vanish quite out of the understanding, leaving no more footsteps or remaining characters of themselves, than shadows do flying over fields of corn; and the mind is as void of them, as if they had never been there.

3. It is sufficiently strong, to retain, for a considerable time, those words or thoughts which are committed to its care. 4. It possesses the power of suggesting and recollecting, from the abundance of its store, words or thoughts proper for every occasion in life.

Rules for Improving the Memory.—Many rules have been given for the regulation of this important faculty: the following, if attentively practised, will conduce much to the solid and lasting improvement of the memory.

Temperance in eating, drinking, and sleep.—The memory depends much upon the state of the brain, and therefore what is hurtful to the latter must be prejudicial to the former. Too much sleep clouds the brain, and too little overheats it; therefore, either of these extremes ought to be avoided. Intemperance of all kinds, and excess of passion, have the same ill effects.

A clear and distinct apprehension of what we wish to remember. We should understand the subject thoroughly, and fix our view particularly upon its importance.

An abridgment of a good book is, sometimes, a very useful exercise.—In general we should preserve the doctrines, sentiments, or facts, that occur in reading; we should lay the book aside, and put them in our own words.

Method and regularity are essentially necessary.—Those things are best remembered, the parts of which are methodically disposed and mutually connected.

Repetition and review.—When a person is hearing a sermon, or a lecture, he should endeavour to recollect the several heads of it, from the beginning, two or three times before the discourse is finished. The omission or the loss of a few sentences is amply compensated by preserving in the mind the method and order of the whole discourse, in all its most important branches. Discoursing with our companions on what we have been reading, or teaching it to our younger friends, is an excellent mode of repetition, and contributes, more than any other perhaps, to assist the memory. The memory gains great advantage by having the objects of our learning drawn out into schemes or tables. The situation of the several parts of the earth is better learned by one day's consultation with the terrestrial globe, than by merely reading the description of their situation a hundred times over in books of geography. Writing what we wish to remember once, and giving it due attention, will fix it more in the mind than reading it several times. What we have seen is not so soon forgotten as what we have only heard. What Horace affirms of the mind or passions, is not less applicable to the memory:

Sounds which address the ear are lost and die
In one short hour; but that which strikes the eye
Lives long upon the mind; the faithful sight
Engraves the knowledge with a beam of light.

Rhyme. The memory of useful things may receive considerable aid, if they are thrown into verse. For the numbers and measures, and rhyme, according to the poesy of different languages, assist us very materially in receiving what is proposed to our observation, and in preserving it long in our remembrance. How many of the common affairs of human life taught in early years are indelibly fixed in our memories by the aid of rhyme.

Initial Letters.—It has sometimes been the practice to imprint names or sentences on the memory, by taking the first letter of every word of that sentence, or of those names, and making a new word out of them. The name of the *Maccabees* is borrowed from the first letter of the Hebrew words which make the sentence, *Mi Camoka, Baclim Jehovah*, that is, Who is like thee among the gods?—which was written on their banners. So the word *Vibgyor* teaches us to remember the order of the seven original colours as they appear by the sun-beams, cast through a prism on white paper, or formed by the sun in a rainbow, according to the different refrangibility of the rays, viz. violet, indigo, blue, green, yellow, orange, and red.

Common Place Book.—There have been many different modes of keeping this book offered to our attention, and almost every person has one peculiar to himself. That which Mr. Locke found, after twenty years' experience, to be the most convenient and advantageous, is thus described. The first page of the book, or, for more room, the two first pages fronting each other,

are to serve for a kind of index to the whole, and contain references to every place or matter therein; in the commodious contrivance of this, so as it may admit of a sufficient variety of materials, without confusion, all the secret of the method consists. The manner of it, as laid down by Mr. Locke, will be conceived from the following specimen, wherein what is to be done in the book for all the letters of the alphabet, is here shewn in the first four.

A	a
	e
	i
	o
	u
B	a
	e 2. 3.

	u

The index of the common place book being thus formed, it is ready for the taking down any thing therein. In order to this, consider to what head the thing you would enter is most naturally referred, and under which one would be led to look for such a thing; in this head or word regard is to be had to the initial letter, and the first vowel that follows it; which are the characteristic letters whercon all the use of the index depends. Suppose I would enter down a passage that refers to the head beauty; B, I consider, is the initial letter, and *e* the first vowel, then looking upon the index of the partition B, and therein the line *e* (which is the place for all words whose initial is B, and the first vowel *e*; as beauty, beneficence, bread, bleeding, blemishes, &c.) and finding no numbers already written to direct me to any page of the book where words of that characteristic have been entered, I turn forward to the first blank page I find, which in a fresh book, as this is supposed to be, will be page 2, and here write what I have occasion for on the head beauty; beginning the head in the margin, and indenting all the other subservient lines, that the head may stand out and shew itself; this done, I enter the page where it is written, viz. 2, in the space B *e*; from which time the class B *e*, becomes wholly in possession of the second and third pages, which are consigned to letters of this characteristic.

Note. If the head be a monosyllable beginning with a vowel, the vowel is at the same time both the initial letter and the characteristic vowel; thus the word *Art* is to be written in A *a*. Mr. Locke omits three letters of the alphabet in his index, viz. K, Y, and W, which are supplied by C, I, and U, equivalent to them; and as for Q, since it is always followed by an *u*, he puts it in the first place of Z; and so has no Z *u*, which is a characteristic that very rarely occurs. By thus making Q the last of the index, its regularity is preserved without diminishing its extent. Others choose to retain the class Z *u*, and assign a place for Q *u* below the index.

If any imagine these hundred classes are not sufficient to comprehend all kinds of subjects without confusion, he may follow the same method, and yet augment the number to 500, by taking in one or more characteristic to them. But the in-

ventor assures us, that in all his collections for a long series of years, he never found any deficiency in the index as above laid down.

The most effectual method of improving the memory is by due and proper exercise. Our memories will be in a great measure molded and formed, improved or injured, according to the exercise of them. If we *never* use them, they will be almost lost. Those who are accustomed to converse and read of a few things only, will retain but a few in their memory. Those who are used to remember an event for an hour, and to charge their memories with it no longer, will retain this event but an hour before it vanishes. But, on the other hand, especial care should be taken, that the memory of the learner be not crowded with too great a variety of ideas at one time. This is the way to learn nothing; one idea effaces another.

The Memory can be improved only by moderate exercise.—Such is the opinion of Dr Watts, a high authority in matters of this nature, respecting the improvements of the natural memory. The recollection which ordinary memories possess, appears to be resolvable into two principal sources, the *vivacity* of the impression, and *association*. Singularity of impression is generally accompanied with vivacity, but association is the principal expedient for assisting the memory. Thus “when I see the house of my friend, I recollect his family; when I hear of Waterloo, I recollect the overthrow of Napoleon.”

MOAT, or DITCH, in Fortification, a deep trench dug round the rampart of a fortified place, to prevent surprises. The brink of the moat next the rampart, is called the scarp; and the opposite one, the counterscarp. A dry moat round a large place, with a strong garrison, is preferable to one full of water; because the passage may be disputed inch by inch, and the besiegers, when lodged in it, are continually exposed to the bombs, grenades, and other fire-works, which are thrown incessantly from the rampart into their works. In the middle of dry moats, there is sometimes another small one called lunette, which is generally dug so deep till they find water to fill it. The deepest and broadest moats are accounted the best, but a deep one is preferable to a broad one; the ordinary breadth is about twenty fathoms, and the depth about sixteen. To drain a mote that is full of water, they dig a trench deeper than the level of the water, to let it run off, and then throw hurdles upon the mud and slime, covering them with earth or bundles of rushes, to make a sure and firm passage.

MOBILITY, a contingent property of bodies, but most essential to their constitution. Every body at rest can be put in motion, and if no impediment intervenes, this change may be effected by the slightest external impression. Thus, the largest cannon ball, suspended freely by a rod or chain from a lofty ceiling, is visibly agitated by the horizontal stroke of a swan shot, which has gained some velocity in its descent through the arc of a pendulum. In like manner, a ship of any burden is, in calm weather and smooth water, gradually pulled along even by the exertions of a boy. A certain measure of force, indeed, is often required to commence or to maintain the motion; but this consideration is wholly extrinsic, and depends on the obstacles at first to be overcome, and on the resistance which is afterwards encountered. If the adhesion and intervention of other bodies were absolutely precluded, motion would be generated by the smallest pressure, and would continue with undiminished energy.

MODE, in Logic, called also syllogistic mood, a proper disposition of the several propositions of a syllogism, in respect of quantity and quality.

MODE, in Philosophy, denotes the manner of a thing's existence.

MODEL, in a general sense, an original pattern, proposed for any one to copy or imitate. This word is particularly in building, as applicable to an artificial pattern made in wood, stone, plaster, or other matter, with all its parts and proportions, in order for the better conducting and executing some great work, and to give an idea of the effect it will have when finished. They also use models in painting and sculpture; whence in the academies of painting they give the term Model to a naked man or woman, disposed in several postures, to afford an opportunity to the scholars to design him in various views and attitudes. Models in imitation of any natural or artificial substance, are

most usually made by means of moulds composed of plaster of Paris. Thus, when a model is to be taken, the surface of the original is first greased, to prevent the plaster from sticking to it. The original is then laid on a smooth table, previously greased, or covered with a cloth to prevent the plaster sticking to it; then surround the original with a frame or ridge of glaziers' putty, at such a distance from it as will admit the plaster to rest upon the table, on all sides of the subject, for about an inch, or as much as is sufficient to give the proper degree of strength to the mould. A sufficient quantity of plaster is then to be poured as uniformly as possible over the whole substance, until it is every where covered to such a thickness as to give a proper substance to the mould, which may vary in proportion to the size. The whole must then remain in this condition till the plaster has attained its hardness: when the frame is taken away, the mould may be inverted, and the subject removed from it; and when the plaster is thoroughly dry, let it be well seasoned.

MODULATION, in Music, the art of conducting harmony, in composition, or extemporary performance, through those keys and modes which have a due relation to the fundamental or original key.

MODUS DECIMANDI, in Law, is where money, land, or other valuable consideration, has been given, time out of mind, to the minister or parson of any certain place, in the room of tithes.

MOHAIR, the hair of a kind of goat, frequent about Angora, in Turkey.

MOISTURE, a term sometimes used to denote animal fluids, the juices of plants, or dampness of the air or other bodies.

MOLE, a name given in the Mediterranean to a long pier or artificial bulwark of masonry, extending obliquely across the entrance of a harbour, in order to break the force of the sea from the vessels that are anchored within.

MOLE, is also applied to the harbour or haven which is formed by the bulwark above described, which latter is then denominated the mole head.

MOLECULÆ, the same as **ATOMS**.

MOLLUSCA, in Natural History, the second order of the Linnæan class vermes. They are naked; furnished with tentacula, or arms; for the most part inhabitants of the sea; and, by their phosphoreous quality, illuminate the dark abyss of the waters. This order is composed of simple animals furnished with limbs.

MOLOSSES, the thick fluid matter remaining after the sugar is made, resembling syrup.

MOLYBDATES, in Chemistry, salts formed from the molybdic acid, and the earths, alkalies, &c. They are colourless, and soluble in water; they have a metallic taste. The prussiate of potash throws down from several of them a light brown-coloured precipitate.

MOLYBDENA, or Sulphuret of Molybdenum, occurs massive, disseminated, and rarely crystallized. Its colour is like that of fresh cut metallic lead. It occurs in granular distinct concretions; it is opaque, stains the fingers, and leaves shining traces when drawn over paper; it is very soft, and easily divisible in the direction of the laminae. Specific gravity 4.5 to 4.7. It is infusible before the blow-pipe, but exhales a sulphureous odour; at a very high heat it melts, gives out white fumes, and burns with a blue flame. It is found in Norway, Sweden, Saxony, and in Mont-Blanc in Switzerland.

MOLYBDENUM, a metal of a grayish-white colour, in the form of brittle infusible grains. In the analysis was obtained sulphur, and a whitish powder, which is a metallic oxide, and possesses the properties of an acid. Hitherto this metal is only obtained in grains, the greatest heat has not been sufficient to melt it into a button; Its specific gravity is 7.4.

MOLYBDIC or **MOLYBDIC ACID**. (See above.) Molybdic acid combines with alkalies, earths, and several metallic oxides, and forms molybdates, which see. This acid, combined with potash, forms a colourless salt; mixed with filings of tin and nitric acid, it becomes blue, and precipitates flakes of the same colour, which disappear after some time; 100 parts are composed of 67 molybdenum, and 33 oxygen.

MOLYNEAUX, WILLIAM, a celebrated astronomer and

mathematician, was born at Dublin, in the year 1666, and died in 1698.

MOLYNEAUX, Samuel, son of the former, was also an able astronomer; but his public situation prevented him from pursuing the subject to the same extent as had been done by his father.

MOMENT, an indefinite small portion of time, having the same relation to duration as a point has to a line.

MOMENT, in the Modern Analysis, is the same as *Infinitesimal*, *Increment*, or *Decrement*; for an explanation of which see those terms.

MOMENTUM, in Mechanics, is the same with impetus, or quantity of motion, and is generally estimated by the product of the velocity and mass of the body. This is a subject, however, which has led to various controversies between philosophers, some estimating it by the mass into the velocity, as stated above, while others maintain, that it varies as the mass into the square of the velocity. But this difference seems to have arisen rather from a misconception of the term, than from any other cause: those who maintain the former doctrine, understanding momentum to signify the momentary impact; and the latter, as the sum of all the impulses till the motion of the body is destroyed. See **FORCE**.

MOMORDICA ELATERIUM. *Spiriting Cucumber*.—The fruit of the Elaterium is a strong cathartic, and very often operates also upwards. Two or three grains are accounted in most cases a sufficient dose. Simon Paulli relates some instances of the good effects of this purgative in dropsies: but cautions practitioners not to have recourse to it till after milder medicines have proved ineffectual; to which caution we heartily subscribe. Medicines indeed, in general, which act with violence in a small dose, require the utmost skill to manage them with any tolerable degree of safety: to which may be added, that the various methods of making these kinds of preparations, as practised by different hands, must needs vary their power.

MONADES. See **DIGITS**.

MONARCHY, a government in which the supreme power is invested in a single person. There are several kinds of monarchies, as, where the monarch is invested with an absolute power, and is accountable to none but God; or limited, where the supreme power is virtually in the laws, though the majesty of government and the administration is vested in a single person. Monarchies are also either hereditary or elective, where the choice depends upon all who enjoy the benefit of freedom, or upon a few persons in whom the constitution vests the power of election.

MONASTERY, a convent, or house built for the reception and entertainment of monks, mediant friars, or nuns, whether it be an abbey, priory, &c.

MONEY, the medium of commerce, commonly metal, and generally of a determined shape and weight to which public authority has affixed a certain value. Money is usually divided into real or effective; and imaginary, or money of account. Real money includes all coins or species of gold, silver, copper, &c. which exist and have currency. Imaginary money, or money of account, is that which has never existed, or at least which does not exist in real specie, but is a denomination invented or retained to facilitate the stating of accounts, by keeping them still on a fixed footing, not to be changed like current coins. No person is obliged to take in payment any money which is not lawful metal, that is, of silver and gold, except for sums under sixpence. But it was decided in Hilary term, 1790, that bank notes were considered as money, and therefore a proper tender in payment.

English Money of Account, is the pound, shillings, and pence, the pound contains twenty shillings, and the shilling twelve pence. Originally the pound was one pound weight of silver, which was coined into twenty shillings, and a penny was a pennyweight, or the 240th part of a pound. In Scotland, the denominations were the same, but the pound of silver was gradually coined into more and more shillings, until at last the pound was reduced to only one-twelfth part of the value of the present pound sterling.

French Money of Account is francs and centimes: sous still appear sometimes in accounts, and 20 of them make a franc.

MONEY bringing into Court. In some actions of law the defendant is allowed to pay a sum into court, which he contends is the fair amount of the plaintiff's just demand, and the plaintiff will afterwards proceed at his peril.

MONOCEROS, the *Unicorn*, is a modern constellation formed by that great innovator Hevelius, out of the stellar informes of the ancients—*Boundaries and Contents*: N. by Gemini, Canis Minor, and Hydra; E. by Hydra; S. by Argo Navis and Canis Major; and W. by Orion. There are thirty-one stars assigned to this constellation in the Britannic Catalogue, viz. ten of the fourth magnitude, and the remainder of smaller magnitudes.

MONOCHORD, in Music, an instrument so called because it is furnished with only one string. Its use is to measure and adjust the ratios of the intervals, which it effects by the means of moveable bridges calculated to divide the chord at the pleasure of the performer.

MONOCULUS, in Natural History, a genus of insects of the order aptera. There are about 50 species, separated into sections.

MONODON, the *Narwhal*, in Natural History, a genus of mammalia, of the order cetæ. The only genus of this species is *M. monoceros*, or the unicorn narwhal, found in the northern seas, and generally of the length of twenty feet from the mouth to the tail; from a socket in the upper jaw on one side, a tooth somewhat resembling a horn grows in a perfectly straight direction, and a wreathed or screw-like form, to the length of six, and occasionally nine or ten feet, of a light yellow colour, and terminating in a sharp point, a circumstance by which it is discriminated from every other species of whales. The incipient protrusion of a second tooth on the other side of the jaw is generally perceivable, and in some instances, though rarely, both advance to maturity. The narwhals subsist principally upon flat-fish. They are seldom observed in the open sea, and frequent the unfrozen spots near the coasts of the arctic regions. They are taken by the Greenlanders in great abundance by the harpoon; their flesh is eaten prepared in various ways, and the oil and intestines are also articles in great request. The tendons are split into thin fibres, serving the purposes of thread, and the teeth are used sometimes for hunting horns, and more frequently as pillars and gate posts in houses. These horns were formerly considered as indicative of royal state and magnificence, being employed as the ornaments of palaces.

MONOGRAM, a character or cipher, composed of one, two, or more letters interwoven; being a kind of abbreviation of a name, anciently used as a seal, badge, arms, &c. The use of arms is very ancient, as appears from Plutarch, and from some Greek medals of the time of Philip of Macedon and Alexander his son. The Roman labarum bore the monogram of Jesus Christ, which consisted of two letters, a P placed perpendicularly through the middle of an X, as we find it on many medals in the time of Constantine, these being the two first letters of the word ΧΡΙΣΤΟΣ. Thus, under the Eastern empire, it is usual to find MIK, which are the monogram of Mary, Jesus, Constantine.

MONOMIAL, in Algebra, is a quantity consisting only of one term; as ax , $3bx^2$, &c.

MONOTONY, an uniformity of sound, or fault in pronunciation, when a long series of words are delivered in one unvaried tone.

MONS MENSÆ, the *Table Mountain*, a modern asterism, situated between the Southern Pole of the World and the Ecliptic, contains thirty stars: this constellation culminates with Auriga and Orion.

MONSOON, a species of trade wind in the East Indies, which for six months blows constantly the same way, and the contrary way the other six months. However, it ought to be observed, that the points of the compass from whence the monsoons blow, as well as the times of their shifting, differ in different parts of the Indian ocean. The cause of monsoons is this: when the sun approaches the northern tropic, there are countries, as Arabia, Persia, India, &c. which become hotter, and reflect more heat than the seas beyond the equator, which the sun has left; the winds, therefore, instead of blowing from thence to the parts under the equator, blow the contrary way; and when the sun leaves those countries, and draws near

the other tropic, the winds turn about, and blow on the opposite point of the compass.

MONTGOLFIER, a name sometimes given to those balloons which receive their buoyancy from the burning of combustible materials; being thus denominated after the name of their inventor, by which name they are also distinguished from the inflammable air-balloons. See AEROSTATION.

MONTH, the twelfth part of the year, and is so called from the moon, by whose motions it was regulated, being properly the time in which the moon runs through the zodiac. The lunar month is either *illuminative*, *periodical*, or *synodical*.

Illuminative MONTH, is the interval between the first appearance of one new moon and that of the next following. As the moon appears sometimes sooner after one change than after another, the quantity of the illuminative month is not always the same. The Turks and Arabs reckon by this month.

Lunar Periodical MONTH, is the time in which the moon runs through the zodiac, or returns to the same point again; the quantity of which is $27^d 7^h 43^m 8^s$.

Lunar Synodical MONTH, called also a lunation, is the time between two conjunctions of the moon with the sun, or between two new moons; the quantity of which is $29^d 12^h 44^m 3^s 11''$. The ancient Romans used lunar months, and made them alternately of twenty-nine and thirty days. They marked the days of each month by three terms, viz. *Calends*, *Nones*, and *Ides*.

Solar MONTH, is the time in which the sun runs through one entire sign of the ecliptic; the mean quantity of which is $30^d 10^h 29^m 5^s$, being the twelfth part of $365^d 5^h 49^m$, the mean solar year.

Astronomical or *Natural* MONTH, is that measured by some exact interval corresponding to the motion of the sun or moon; such are the lunar and solar months above mentioned.

Civil or *Common* MONTH, is an interval of a certain number of whole days, approaching nearly to the quantity of some astronomical month. These may be either lunar or solar.

The *Civil Lunar* MONTH consists alternately of twenty-nine and thirty days. Thus will two civil months be equal to two astronomical ones, abating for the odd minutes; and so the new moon will be kept to the first day of such civil months for a long time together. This was the month in civil or common use among the Jews, Greeks, and Romans, till the time of Julius Cæsar.

The *Civil Solar* MONTH, consisted alternately of thirty and thirty-one days, excepting one month of the twelve, which consisted only of twenty-nine days; but every fourth year of thirty days. The form of civil months was introduced by Julius Cæsar. Under Augustus, the sixth month, till then from its place called Sextilis, received the name Augustus, now August, in honour of that prince; and to make the compliment still greater, a day was added to it, which made it consist of thirty-one days, though till then it had only contained thirty days; to compensate for which, a day was taken from February, making it consist of twenty-eight days, and twenty-nine every fourth year. Such are the civil or calendar months now used through Europe.

MONTH, in Law, is generally a lunar month of twenty-eight days, unless otherwise expressed.

MONTUCLA, JOHN ETIENNE, a celebrated French mathematician, was born at Lyons, September 5, 1725; and very early in the College of the Jesuits acquired a very intimate knowledge of the Latin and Greek languages, to which he added also several modern languages, as the Italian, English, German, and Dutch; which, joined to a very complete knowledge of the mathematical and philosophical sciences, and a remarkable accuracy of research, eminently qualified him for the performance of that work by which he is most distinguished, and by which he has laid a lasting obligation on every admirer of these sciences, viz. his "*Histoire des Mathematiques*," which first appeared in 1758, in 2 vols. 4to. and which has been since, viz. in 1802, republished, and augmented to 4 vols. 4to. by Lalande; the additions being principally drawn from the numerous manuscript notes left by Montucla at the time of his death, which happened at Paris, December 18, 1799.

MONUMENT, in Architecture, a building destined to preserve the memory, &c. of a person who raised it, or for whom it was raised; as, a triumphal arch, a mausoleum, a pyramid, &c.

MOOD, or **MODE**, in Grammar, the different manner of conjugating verbs, serving to denote the different affections of the mind.

MOON, *Luna*, in Astronomy, one of the heavenly bodies, the constant attendant of our earth, about which she revolves as a centre, illuminating us by her reflected rays in the absence of the sun. The principal elements and phenomena of this body are thus stated by Mr. Baily, in the *Philosophical Magazine* for January, 1812, in a very neat and useful synopsis of astronomy, drawn principally from the *Système Du Monde* of Laplace. The motions of the moon are exceedingly eccentric and irregular. She performs her mean *sidereal* revolution in $27^d\ 7^h\ 43^m\ 11^s.5$; but this period is variable, and a comparison of the modern observations with the ancient proves incontrovertibly an *acceleration* in her mean motion. Her mean *tropical* revolution is $27^d\ 7^h\ 43^m\ 4^s.7$, and her mean *synodical* revolution $29^d\ 12^h\ 44^m\ 2^s.8$. Her mean distance from the earth is 29,982,175 times the diameter of the terrestrial equator, or about 237,000 miles. The *eccentricity* of her orbit is .0548553; the mean distance from the earth being taken equal to unity; but this eccentricity is variable in each revolution. Her mean *longitude*, at the commencement of the present century, was in $3^s\ 21^o\ 30' 42".1$. Her *velocity* varies in different parts of her orbit; she is swiftest in her perigee (or point nearest the earth,) and slowest when in her apogee (or point farthest from the earth); her mean diurnal velocity is equal to $13^o\ 10' 34".9$, or about thirteen times greater than that of the sun. The greatest *equation* of her centre is $6^o\ 17' 54".5$. The mean longitude of her *perihelion* was, at the commencement of the present century, in $8^s\ 26^o\ 6' 5".1$; but the line of the apsides has a motion, according to the order of the signs. The period of a sidereal revolution of the apsides, is $323^d\ 2^h\ 13^m\ 56^s\ 16^s.8$, or nearly nine years. The period of a tropical revolution of the apsides, is but $323^d\ 1^h\ 24^m\ 8^s.6$. But these periods are not uniform, for they have a secular irregularity, and are retarded whilst the motion of the moon itself is accelerated. The period of an *anomalous* revolution of the moon is $27^d\ 13^h\ 18' 37".4$. Her orbit is inclined to the plane of the ecliptic in an angle of $5^o\ 9'$; but this inclination is variable. The greatest inequality, which sometimes extends to $8' 47".51$, is proportional to the cosine of the angle on which the inequality in the motion of the nodes depends. Her orbit, at the commencement of the present century, crossed the ecliptic in $0^s\ 15^o\ 55' 26".3$; but the place of her nodes is variable; these having a retrograde motion, and make a sidereal revolution in $6793^d\ 10^h\ 6' 30".0$, or in about 186 Julian years. This variation, however, is subject to many inequalities; of which, the greatest is proportional to the sine of double the distance of the moon from the sun, and extends to $1^o\ 37' 45".0$ at its maximum. A synodical revolution of the nodes is performed in $346^d\ 14^h\ 52^m\ 43^s.6$; but the motion of the nodes is subject also to a secular inequality, dependent on the acceleration of the moon's mean motion.

The rotation of the moon on her axis is equal and uniform, and is performed in the same time as the tropical revolution in her orbit; whence she always presents nearly the same face to the earth. But as the motion of the moon in her orbit is periodically variable, we sometimes see more of her eastern edge, and sometimes more of her western edge; which appearance is called the *libration* of the moon in *longitude*. The axis of the moon is inclined to the plane of the ecliptic in an angle of $85^o\ 28' 49"$; in consequence of which position of the moon, her poles alternately become visible to and obscured from us; and this phenomenon is called her *libration* in *latitude*. There is also another optical deception, arising from the moon being seen from the surface of the earth, instead of the centre, which is called her *diurnal libration*.

Excellent drawings of the moon have been made by Tobias Mayer, and Russel; but the most accurate and complete are those of Schroeter, who has given highly magnificent views of several parts of the moon's surface. The most favourable time for viewing the lunar disc, is when she is about five days old; the irregularities in her surface being then the most conspicuous.

It is impossible to say what those unenlightened portions, observable in the disc, are, or what they may have been, but we cannot help thinking that our earth would assume nearly the

same appearance, if all the lakes and seas were removed; and who can say but that this may have been the case in the lunar regions? Astronomers formerly supposed, that the dark part of the moon's surface were large lakes and seas, but it is obvious, on an attentive observation with a good telescope, that there are ridges and unevennesses in those parts, which plainly indicate that they are not fluid but solid, like the other parts of her surface; there is, therefore, very little of any fluid matter in this luminary, and hence probably is the reason that her atmosphere is so different from our own; if, indeed, this can be justly inferred from the circumstances usually adduced as arguments in favour of this hypothesis, which appears very doubtful. We have observed, that mountains may always be seen on the surface of the lunar disc; and even volcanoes have been frequently observed, from which some philosophers have supposed the *æroliths*, that at times fall to the earth, to have been projected; which it appears, from computation, would only require a velocity of about 8200 feet per second, to cause them to pass from this body to the earth. See ASTRONOMY.

Acceleration of the Moon. See ACCELERATION.

Age of the Moon, is the number of days since the new moon, which is found by the following rule:—To the *epoch* add the number and day of the month, which will be the age required, if less than thirty; and if it exceed thirty, subtract this number from it, and the remainder will be the age. See EPOCH.

Harvest Moon, is a remarkable phenomenon relating to the rising of this luminary in the harvest season. During the time she is at the full, and for a few days before and after, in all about a week, there is less difference in the time of her rising between any two successive nights at this than at any other time of the year. By this means she affords an immediate supply of light after sun-set, which is very beneficial in gathering in the fruits of the earth; and hence it is, that this lunation has been termed the harvest moon. In order to conceive this phenomenon, it may first be considered, that the moon is always opposite to the sun when she is full; that she is full in the signs Pisces and Aries in our harvest months, these being the signs opposite to Virgo and Libra, the signs occupied by the sun about the same season; and because those parts of the ecliptic rise in a shorter space of time than others, as may easily be shewn and illustrated by the celestial globe, consequently when the moon is about her full in harvest, she rises with less difference of time, or more immediately after sun-set, than when she is full at other seasons of the year.

Moon Dial, is a dial which shews the hours of the night by the light of the moon.

MOOR, To, to confine or secure a ship in a particular station by chains or cables, which are either fastened to the adjacent shore, or to anchors in the bottom; a ship is never said to be moored when she rides by a single anchor.

To Moor Across, is to lay out one of the anchors on one side, or athwart a river, and another on the other side right against it. *To Moor Along*, is to have an anchor in the river, and a hawser on shore. *To Moor a Cable each way*, is performed by dropping one anchor, veering out two cables' lengths, and letting go another anchor from the opposite bow; the first is then hove in to one cable, while the latter is veered out as much, whereby the ship rides between the two anchors, equally distant from both. This is usually practised in a tide-way, in such manner that the ship rides by one during the flood, and by the other during the ebb.

To Moor Head, or Head and Stern. This operation may be performed by two methods:—A ship may be secured by anchors before her, without any behind; or she may have anchors out, both before and behind her; or her cables may be attached to posts, rings, or moorings, which answer the same purpose. When a ship is moored by the head with her own anchors, they are disposed according to the circumstances of the place where she lies, and the time she is to continue therein. Thus, whenever a tide ebbs and flows, it is usual to carry one anchor out towards the flood, and another towards the ebb, particularly where there is little room to range about; and the anchors are laid in the same manner, if the vessel is moored head and stern in the same place. The situation of the anchors in a road or bay, is usually opposed to the reigning winds, or to those which are most dangerous, so that the ship rides therein

is loaded with an unnecessary weight of metal: the ber thereof contains thirty-two pounds of powder, and at the same time they are never charged with more than twelve pounds by the most expert officers, because the bomb is unable to bear the violent shock of their full charge.

The action of the powder is diminished by the vacancy of the chamber, which is never half filled. As a charge of five or fifteen pounds at most is therefore sufficient, it is easily proved, by the theory of powder, that this will produce the greatest effect when discharged from a mortar with a spherical chamber. He also proves, by a variety of experiments made by Captain Desaguliers and himself, that the spherical chamber, now used, is considerably inferior to the conical one with the last discharge of powder. To facilitate the use of the mortar, it is placed in a solid carriage of iron called the bed, whose different parts are strongly bolted together. By means of this it is firmly secured in its situation, so that the explosion of the powder may not alter its direction. The middle of the upper side of this carriage are two semicircular notches to receive the trunnions; over these are fixed very strong bands of iron, called the cap squares, the ends of which is bent into a semi-circle, to embrace the trunnions, and keep them fast in the mortar bed. The cap squares are confixed to the timber work by strong pins of iron, and the eye-bolts, into whose upper ends are driven the chains beneath them. On the fore-part of the bed a piece of timber is placed transversely, upon which rests the mortar on that part which contains the chamber. The elevation of this piece, which is called the bed bolster, is to elevate and support the mortar whilst firing. These are placed upon very strong beds of timber, which are in the bomb-ketch. They are securely attached to the vessel by means of a strong bolt of iron called the pintle, passing perpendicularly through both, and afterwards through one of the beams of the vessel. Thus the pintle which passes through the whole in the centre, serves as an axis to the bed, so that the mortar may be turned about horizontally as occasion requires. The shell, as already observed, is a great hollow ball, charged with powder. The lower part of the shell is strengthened, by which it becomes heavier on that side, and accords with the nature of the explosion, and never on the fuse. It is also the better adapted thereby to resist the impression of the powder, by which it is discharged from the mortar. Both of these reasons, however, Mr. Muhler conceives to be immaterial, because nothing but an absolute stoppage of the air can exhaust the powder, as their composition enables them to burn in water as well as in air or earth, and the explosion of the mortar would, in his opinion, be able to break them, if they were equally strong every where. The most proper quantity of powder to charge a shell is probably two-thirds of the weight which would fill the cavity. The fuse is generally a conical tube formed of willow, or some dry wood, and filled with a composition of sulphur, salt-petre, and meal powder. The shell being prepared, this fuse is inserted in the cavity through the fuse-hole when fired, communicates the fire to the powder in the chamber. The fuses are charged with great care, that nothing prevent them from communicating the fire to the powder in the centre of the bomb. They are driven into it so as that a inch and a half comes out beyond the fuse-hole, and the shell is said to be fixed. These fuses are also charged before there is occasion to use them; and that the composition with which they are filled may not fall out or be damaged by lying damp, the two ends are covered with a composition of tallow mixed either with pitch or bees-wax. When the mortar is to be put into the shell, the little end is opened or split, but the great end is never opened till the mortar is to be fired. The proper quantity of gunpowder being put into the chamber, if there be any vacant space, they fill it up with some choice a wooden plug; over this they lay a turf, a stopper fitted to the bore of the piece, and lastly the mortar, taking care that the fire be in the axis thereof, and the mortar be turned from the muzzle of the piece. What space remains is to be filled up with hay, straw, turf, &c. so as that the mortar may not be exploded without the utmost violence. When done, the charge is covered with a wad well beat down with the rammer. After this the fixed shell is placed upon the

wad, as near the middle of the mortar as possible, with the fuse-hole uppermost, and another wad pressed down close upon it, so as to keep the shell firm in its position. The officer then points the mortar, or gives it the inclination necessary to throw the shell to the place designed. When the mortar is thus fixed, the fuse is opened; the priming-iron is also thrust into the touch-hole of the mortar to clear it, after which it is primed with the finest powder. This done, two of the matrosses or sailors, taking each one of the matches, the first lights the fuse, and the other fires the mortar. The shell, thrown out by the explosion of the powder, is thrown to the place intended; and the fuse, which ought to be exhausted at the instant of the shell's falling, inflames the powder contained therein, and bursts it into splinters; which, flying off circularly, occasion incredible mischief wheresoever they reach.

The following are the necessary orders before a bombardment by sea:—When any fixed shells are issued from the tenders, the artillery people on board are immediately to fix others in their room, and are always to keep in their tenders the same number they had at first. 2. The shells are to be fixed in the boats appointed to carry them, provided the weather permits; otherwise, in the safest place on deck, and to be kited or lowered down into a spare rack, which must be in each boat for that purpose. While the shells are fixing, the powder-room is to be shut, the hatches laid and well secured against fire, and the place where they are fixed is to be well watered. 3. The shells being carefully examined, in order that no spike be left therein, by which the fuse may be split, the fuses are to be cut the whole length, and to be set home into the shells very strongly. 4. No shells fixed during the service are to be kited; but if any should be left when the service is over, they are immediately to be kited. 5. The powder in the bomb-vessels is to be used first, and none to be opened or measured out except in the captain's cabin, the door of which is to be kept shut during the whole time, and covered with tanned hides to make it as secure as possible. 6. The fixed shells in the boats are to be likewise covered from fire or wet, with hair-cloth and tanned hides with the utmost care. 7. If the service is carried on at night, all the powder is to be ready measured out in cartridges, which may be kept in the powder-magazine and captain's cabin in the empty powder barrels and powder bags; and all the shells requisite to be ready. The tin tubes, one powder horn, and the port-fires, also the punches and bits for the vents, are to be kept in the captain's cabin. 8. No fire, nor light, except match and port-fires, to be on board either bomb-vessel or tender during the service. 9. The captain's cabin and the passage to it, also the way to the magazine and decks, are to be constantly watered. 10. The sponges for the mortars are to be all examined and tried, and if too large, they are to be cut so as to enter easily. 11. The vents of the mortars are to be examined, and the punches and tubes tried in them. 12. A laboratory chest is to be on board each bomb-vessel in the captain's cabin, in which all the small stores are to be kept. 13. Two tubs of water are to be on deck for the lightest port-fires and match, which must be constantly held in them till ordered to fire. 14. Two careful men are also to be appointed for this service, who are to do nothing else on any account. 15. Two careful men of the artillery are to be left on board each tender, for the filling and fixing of the shells. 16. Application must be made to the admiral for two men-of-war's boats to attend on each bomb-ketch and tender for carrying shells and stores. One of these is to be loaded with fixed shells, which, when sent to the bomb-vessel, must remain with her until they are all taken out, which should be only as they are wanted for loading the mortars: it is then to return to the tender. The other boats, meanwhile, will be receiving more fixed shells, and on the signal given from the bomb-ketch for more shells, must immediately repair to her with them. 17. A gang of warrant officers and eight seamen are to be at each mortar, and to give whatever assistance may be required. 18. A gang from the navy, with a careful warrant officer and non-commissioned officer of the artillery, are to have the charge between decks on board each bomb-vessel and tender, to get up the fixed shells that are in the rack, and a careful person is to remain constantly at the powder-room door, which must be kept shut as much as possible. 19. When

any powder is wanted from the tender for loading the mortar, it should be measured out in the tender, and a proper charge put into paper cartridges, upon which should be written the quantity and the mortar for which it is allotted.

In shooting with mortars, the following general rules should be always observed:—1. To measure the distance of the object aimed at. 2. That the bombs be of equal weight, otherwise the shots will vary. 3. That the carriage be on an exact level to prevent its leaping. 4. That the powder with which the piece is charged be always of the same strength and quantity. 5. That the charge be always equally rammed down. 6. That the wads be always of wood, tampions, or oakum. 7. That the fuses be fresh made the days on which they are to be used, and that they be of a composition proportionable to the range of the shot in the air, so that the bomb may break at the very moment of, or soon after, its fall; which composition must be such as not to be extinguished though it fall in water, but continue burning till the bomb breaks.—If the service of mortars should render it necessary to use pound shots, two hundred of them, with a wooden bottom, are to be put into the thirteen-inch mortar, and a quantity of powder not exceeding five pounds; and one hundred of the above shot, with two pounds and a half of powder for the ten-inch mortar, or three pounds at most. One inch of fuse burns four seconds and forty-eight parts.

The following table exhibits the weight of the sea-mortars and shells, and also of their full charge:—

Nature of the mortar.	Powder contained in the chamber when full.		Weight of the mortar.		Weight of the shell when fixed.	Weight of powder contained in the shell.	
	lb.	oz.	C.	qr. lb.	lb.	lb.	oz.
10-inch howitzer.	12	0	31	2 26	0	0	0
13-inch mortar.	30	0	81	2 1	198	7	0
10-inch mortar.	12	0	34	2 11	93	0	0

The Howitzer is a sort of mortar, which is to be fixed horizontally like a cannon, and has, like the cannon, a wheel carriage. These pieces are very rarely used in the sea service. For further particulars, see the articles BOMB, RANGE, &c.

MORTAR.—*Mr. Carey's Improved Plan of a Gun and Mortar Boat, with Sheer Bowsprit.* A port-hole is cut through, and a port fitted, the same as the lower deck port. Combings and gratings are fitted over the gun, which runs in until wanted to the main mast. Over the gratings, a tarpauling is thrown in bad weather; alongside of the mast, a winch, which runs the gun in and out, and hoists the mainsail and foresail, and also tops the sheer bowsprit up when about to fire the gun. With two men, a boy, and an engineer, having a steam-engine on board, and a long 32-pounder with a chamber in the gun, a frigate might be destroyed in a calm, or a seventy-four dismantled and sunk. With a steam-engine on board, and if the larger vessel attempted to hoist out their boats to board the mortar boat, she could run away from them; and, a gun fitted right aft, could destroy the boats and their crews. The sheer bowsprits shew their utility, as no bowsprit shrouds are wanting, nor bobstay, the jib-tack forming the bobstay. Carey, of Bristol, fitted a boat in this way, when at his majesty's yard at Gibraltar, which Lord Nelson highly approved of.

Description. *a a* the sheer bowsprit; *b* the port and port-hole; *c* the 32 long pounder, with a chamber; in bad weather the gun is run under a grating which is over it upon deck; *d* a winch to heave the gun out and in; after firing, hoist the main sail, and heave up the sheer bowsprit; *e* the jib-stay and topping lift, to raise the sheers when going to fire.—N. B. A magazine is placed midway between the gun and the ship's side, which cannot be shewn in the above view.

MORTGAGE, signifies a pawn of lands or tenements, or any thing immoveable, laid or bound for money borrowed, to be the creditor's for ever, if the money be not paid at the day agreed upon. Mortgages are either in fee or for term of years, and the mortgager was formerly considered as tenant at will to the mortgagee, but he is now considered to have no legal estate whatever in the land. The last and best improvement of mortgages is the mode now adopted, where the mortgage is made for a term of years, that the mortgager, if he has also the fee, covenants to convey the fee to the mortgagee and his heirs, or any person whom he may appoint in case of default in payment of the money. Although, after breach of the condition, the estate is absolute at common law in the mortgagee, yet a right of redemption subsists in equity, which is called the equity of redemption, from the benefit of which the heir of the mortgager cannot be excluded by any covenant, provided the original intent is to mortgage the estate, and not to sell it at first. This right goes to those who would have had the estate, if it had not been incumbered. Although therefore the mortgage is forfeited, yet a court of equity will allow the mortgager at any reasonable time, to recall or redeem the estate, paying the principal, interest, and costs. This, however, is not allowed, if the mortgagee has been twenty years in possession. The heir at law may have the mortgage redeemed out of the personal assets in the first place as far as they will extend. This privilege is also allowed to the person to whom land mortgaged is devised. Where a mortgager conceals prior incumbrances upon making a second mortgage, he loses the equity of redemption.

MORTISE, or MORTOISE, in Carpentry, a kind of joint, wherein a hole of a certain depth is made in a piece of timber, which is to receive another piece called a tenon.

MORTMAIN, signifies an alienation of lands and tenements, to any guild, corporation, or fraternity, and their successors, as bishops, parsons, vicars, &c., which may not be done without the king's license, and the lord of the manor; or of the king alone, if it is immediately holden of him.

MORUS, the *Mulberry Tree*, a genus of the tetrandria order, in the monoccia class of plants; natural order scabridæ. There are seven species, viz. 1. The nigra, or common black-fruited mulberry-tree, rises with an upright, large, rough trunk, dividing into a branching and very spreading head, rising twenty feet high or more. The fruit has the common qualities of the other sweet fruits, abating heat, quenching thirst, and promoting the grosser secretions; an agreeable syrup made from the juice is kept in the shops. The bark of the roots has been in considerable esteem as a vermifuge; its taste is bitter, and somewhat astringent. 2. The alba, or white mulberry-tree, rises with an upright trunk, branching twenty or thirty feet high. Considered as fruit trees, the nigra is the only proper sort to cultivate here; the trees being not only the most plentiful bearers, but the fruit is larger and much finer flavoured than that of the white kind. Mulberry-trees are noted for their leaves affording the principal food of the silkworm. The leaves of the white species are preferred for this purpose in Europe; but in China, where the best silk is made, the worms are fed with those of the morus tartarica. The advantages of white mulberry trees are not confined to the nourishment of worms: they may be cut every three or four years like willows and poplar trees to make fagots; and the sheep eat their leaves in the winter, before they are burnt. This kind of food, of which they are extremely fond, is nourishing; it gives a delicacy to the flesh and a fineness to the wool. The paper mulberry, is so called from the paper chiefly used by the Japanese being made of the bark of its branches. The leaves of this species also serve for food to the silkworm, and is now cultivated with success in France. It thrives best in sandy soils, grows faster than the common mulberry, and at the same time it is not injured by the cold. The inhabitants of Japan make paper of the bark, culti-

vate the trees to this purpose on the mountains, much after the same manner as osiers are cultivated with us, cutting down the young shoots in December, after the leaves are fallen; these being divided into rods of three feet in length, are gathered in bundles to be boiled; they are placed erect and close in a large copper, properly closed, and the boiling continued till the separation of the bark shews the naked wood, after which, by a longitudinal incision, the bark is stripped off and dried, the wood being rejected. To purify the bark, they keep it three or four hours in water; when it is sufficiently softened, the cuticle, which is of a dark colour, together with the greenish surface of the inner bark, is pared off, at the same time the stronger bark is separated from the more tender, the former making the whitest and best paper; the latter a dark and inferior kind. The finest and whitest cloth, worn by the principal people at Otaheite, and in the Sandwich islands, is made of the bark of this tree. The bread-fruit tree makes a cloth inferior in whiteness and softness, worn chiefly by the inferior people. Cloth is also made of a tree resembling the wild fig-tree of the West Indies; it is coarse and harsh, the colour of the darkest brown paper; but it is the most valuable, because it resists the water. This is perfumed and worn by the chiefs as a mourning dress in Otaheite. The tinctora is a fine timber tree, and a principal ingredient in most of our yellow dyes, for which it is chiefly imported into Europe.

MOSAIC, or **MOSAIC WORK**, an assemblage of little pieces of glass, marble, precious stones, &c. of various colours, cut square, and cemented on a ground of stucco, in such a manner as to imitate the colours of painting.

MOSCHUS, Musk, a genus of quadrupeds, of the order pecora. The Tibetan musk in size and general appearance resembles the small roebuck. It measures about three feet three inches in length, about two feet three inches in height from the top of the shoulders to the bottom of the fore feet, and two feet nine inches from the top of the haunches to the bottom of the hind feet. The upper jaw is considerably longer than the lower, and is furnished on each side with a curved tusk about two inches long. These tusks are of a different form from those of any other quadruped; being sharp edged on their inner or lower side, so as to resemble in some degree a pair of small crooked knives: their substance is a kind of ivory, as in the tusks of the baly russa and some other animals. They are hunted for the sake of their well-known perfume, which is kept in an small oval receptacle about the size of an egg, hanging from the middle of the abdomen, and peculiar to the animal. This receptacle is found constantly filled with a soft, unctuous, brownish substance, of the most powerful and penetrating smell, and which is no other than the perfume in its natural state. As soon as the animal is killed, the hunters cut off the receptacle or musk bag, and tie it up ready for sale. As musk is an expensive drug, it is frequently adulterated by various substances. As a medicine, it is held in high estimation in the Eastern countries, and has now been introduced into pretty general use, especially in those disorders which are commonly termed nervous; and in convulsive and other cases it is often administered in pretty large doses with great success. The Indian musk is rather larger than the common or Tibetan musk, of the colour mentioned in the specific character, with the head shaped like that of a horse, upright oblong ears, and slender legs. The pigmy musk is considerably smaller than a domestic cat, measuring little more than nine inches from the nose to the tail.

MOSQUE, a temple or place of religious worship among the Mahometans. All mosques are square buildings, generally built with stone; before the chief gate there is a square court, paved with white marble, and low galleries round it, whose roof is supported by pillars. In these galleries the Turks wash themselves before they go into the mosque. In each mosque there are a great number of lamps. As it is not lawful to enter the mosque with shoes or stockings on, the pavements are covered with pieces of stuff sewed together, each wide enough to hold a row of men kneeling, sitting, or prostrate. The women are not allowed to enter the mosques. About every mosque there are six high towers, called minarets, each of which has three little open galleries one above another: whence, instead of a bell, the people are called to prayer by certain officers appointed for that purpose. Most of the mosques have a kind of hospi-

tal belonging to them, in which travellers, of what religion soever, are entertained during three days. Each mosque has also a place called tarbe, which is the burying place of its founders; within which is a tomb six or seven feet long, covered with green velvet or satin, at the end of which are two tapers, and round it several seats for those who read the Koran, and pray for the souls of the deceased.

MOTACILLA, the *Wagtail* and *Warbler*, a genus of birds of the order of passerres, distinguished by a straight weak bill, and very slender legs.—The white wagtail frequents the sides of ponds and small streams, and feeds on insects and worms. The yellow wagtail migrates in the north of England, but in Hampshire continues the whole year. The male is a bird of great beauty; the breast, belly, thighs, and vent-feathers, being of a most vivid and lovely yellow. The colours of the female are more obscure than those of the male; it wants also those black spots on the throat. Under this genus there are several well known birds, which we shall here describe. The gold crested wren belongs to this class, a native of Europe, and of the correspondent latitudes of Asia and America, is the least of all the European birds, weighing only a single drachm. Its length is about four inches and a half, and the wings when spread out measure little more than six inches. On the top of its head is a beautiful orange-coloured spot, called its crest, which it can hide at pleasure.—The tailor bird, belonging also to this class, is a native of the East Indies. It is remarkable for the art with which it makes its nest, seemingly in order to secure itself and its young in the most perfect manner possible against all dangers from voracious animals. It picks up a dead leaf, and sews it to the side of a living one; its slender bill is the needle, and its thread is formed of some fine fibres; the lining is composed of feathers, gossamer, and down.—The nightingale, another of this genus, exceeds in size the hedge sparrow. The bill is brown; the irides are hazel; the head and back pale tawny, dashed with olive; the tail is of a deep tawny red; the under parts pale ash colour, growing white towards the vent; the quills are cinereous brown. The male and female are very similar. This bird, the most famed of the feathered tribe, for the variety, length, and sweetness of its notes, is supposed to be migratory. The female builds in some low bush or quickset-hedge well covered with foliage, for such only this bird frequents, and lays four or five eggs of a greenish brown. The nest is composed of dry leaves on the outside, mixed with grass and fibres, lined with hair or down within, though not always alike. The female alone sits on and hatches the eggs, while the male, not far off, regales her with his delightful song; but as soon as the young are hatched, he commonly leaves off singing, and joins with the female in the task of providing for and feeding them.—The hedge-sparrow, a well-known bird, has the back and wing-coverts of a dusky hue, edged with reddish-brown, rump of a greenish-brown; throat and breast of a dull ash-colour; the belly a dirty white; and the legs of a dull flesh-colour. The note of this bird would be thought pleasant, did it not remind us of the approach of winter.—The redstart is somewhat less than the redbreast; the forehead is white; the crown of the head, hind part of the neck, and back, are deep blue-gray; the cheeks and throat black; the breast, rump, and sides red; and the belly is white; the two middle tail feathers are brown; the rest red; and the legs are black. The wings are brown in both sexes. The red-breast, universally known, builds not far from the ground, if in a bush; though sometimes it fixes on an out-house, or retired part of some old building. The nest is composed of dried leaves, mixed with hair and moss, and lined with feathers. The eggs are of a dusky white, marked with irregular reddish spots; and are from three to seven in number. Insects are their general food; but in defect of these they will eat many other things. No bird is so tame and familiar as this; closely attending the heels of the gardener when he is using his spade, for the sake of worms; and frequently in winter entering houses where windows are open, when they will pick up the crumbs from the table while the family is at dinner. The wheatear is in length five inches and a half. The top of the head, hind part of the neck, and back, are of a bluish gray; and over the eye a streak of white; the under parts of the body yellowish-white; the breast tinged with red; and the legs are

black. This bird is met with in most parts of Europe, even as far as Greenland; and specimens have also been received from the East Indies. The young are hatched in the middle of May. In some parts of England these birds are in vast plenty.

The wren is a very small species, in length only three inches and three-quarters, though some have measured four inches. It generally carries the tail erect. This minute bird is found throughout Europe; and in England it defies our severest winters. Its song is much esteemed, being, though short, a pleasing warble, and much louder than could be expected from the size of the bird; it continues throughout the year.—Above an hundred and fifty species, besides varieties, are enumerated by ornithologists as belonging to this genus.

MOTE, in Law-books, signifies court, meeting, or convention, as a ward-mote, burg-mote, swain-mote, &c.

MOTH, in Zoölogy, is an insect of the winged kind, which, though insignificant in itself, proves destructive to various crops of garden and field productions. Of these insects there is a great variety, and their natural history is both amusing and instructive.

MOTHER OF PEARL, is that beautiful natural white enamel, which forms the greater part of the substance of the oyster-shell, particularly of the pearl oyster.

MOTHER Water, in Chemistry, is the uncrystallizable residue of a compound saline solution: thus the liquor left in a salt pan after the salt is taken out, is the mother-water.

MOTION, or **LOCAL MOTION**, in Mechanics, is a continued and successive change of place, or it is that affection of matter by which it passes from one point of space to another. Motion is of various kinds, as follows:

Absolute MOTION, is the absolute change of places in a moving body, independent of any other motion whatever; in which general sense, however, it never falls under our observation. All those motions which we consider as absolute, are in fact only relative; being referred to the earth, which is itself in motion. By absolute motion, therefore, we must only understand that which is so with regard to some fixed point upon the earth; this being the sense in which it is delivered by writers on this subject.

Accelerated MOTION, is that which is continually receiving constant accessions of velocity. See **ACCELERATED MOTION**.

Angular MOTION, is the motion of a body as referred to a centre, about which it revolves.

Compound MOTION, is that which is produced by two or more powers acting in different directions. See **PARALLELOGRAM OF FORCES**.

Equable MOTION, or **Uniform Motion**, is when the body moves continually with the same velocity, passing over equal spaces in equal times.

Natural MOTION, is that which is natural to bodies, or that which arises from the action of gravity.

Relative MOTION, is the change of relative place in one or more moving bodies; thus two vessels at sea are in *absolute motion* (according to the qualified signification of this term) to a spectator standing on shore, but they are only in relative motion with regard to each other.

Retarded MOTION, is that which suffers continual diminution of velocity, the laws of which are the reverse of those for accelerated motion. See **ACCELERATION** and **RETARDATION**.

Projectile MOTION, is that which is not natural, but impressed by some external cause; as when a ball is projected from a piece of ordnance, &c. See **PROJECTILE**.

Rectilinear MOTION, that which is performed in right lines.

Rotatory MOTION.—*Seaton's Machine for Experiments on Rotatory Motion*. This machine is exhibited in the following figure, where the vertical axis N B is turned by the rope M passing over the pulley R, and carrying the scale S. The axis N B carries two equal leaden weights K, D, moveable at pleasure on the horizontal bar H I. The upper part N of the axis is one half the diameter of the part M, so that when the rope is made to wind round N, it acts at half the distance from the axis, at which it acts when coiled round M. When the rope is wound round N, the same force will produce in the same time but half the velocity which is produced when the rope coils round M, the situation of the leaden weights being the same; but when the weights K, L, are removed to a double

distance from the axis, a quadruple force will be required in order to produce an equal angular velocity in a given time.

Laws of MOTION, as delivered by Newton in his "*Principia*," and on which he has supported the whole system of his philosophy, are the three following:

Every body perseveres in its state of rest, or uniform motion in a right line, until a change is effected by the agency of some external force. Any change effected in the quiescence or motion of a body is in the direction of the force impressed, and is proportional to it in quantity. Action and reaction are equal, and in contrary directions.

When speaking of these axioms, or laws of motion, it ought always to be recollected that they are not the efficient operative causes of any thing. A law presupposes an agent; for it is only the mode, according to which an agent proceeds: it implies a power, for it is the order according to which that power acts. Abstracted from this agent, this power, the law does nothing, is nothing; so that a law of nature or of motion can never be assigned as the adequate cause of phenomena, exclusive of power and agency. The Newtonian axioms are, in reality, intermediate propositions between geometry and philosophy; through which mechanics becomes a mathematical branch of physics, and its conclusions possessed of such coherence and consistency among themselves, and with matter of fact, as are rarely to be found in other branches, which admit not of so intimate a union with the science of quantity.

The evidences from which our assent to these axioms is derived, are of various kinds:—1. From the constant observation of our senses, which tend to suggest the truth of them in the ordinary motion of bodies, as far as the experience of mankind extends. 2. From experiments, properly so called. 3. From arguments *à posteriori*. One or other of these kinds of evidence generally forms a part of our most valuable treatises on mechanics and physics; but there is a fourth way in which the truth of these axioms may be deduced, which is that in which they are shewn to be laws of human thought, intuitive consequences of the relations of those ideas which we have of motion, and of the causes of its production and changes.

MOTION, in Astronomy, is still farther divided into *diurnal, annual, horary, sidereal*, &c.; for which see the respective terms.

MOTION, *Spontaneous* or *Muscular*, is that performed by the muscles at the command of the will.

MOTION, *Natural* or *Involuntary*, that effected without any such command, by the mere mechanism of the parts, such as the motion of the heart, pulse, &c.

MOTION, *Intestine*, the agitation of the particles of which a body consists.

MOTION, in Music, the manner of beating the measure, to hasten or slacken the time of the words or notes.

MOTRIX, that which has the power or faculty of moving.

MOULD, or **MOLD**, in the Mechanic arts, &c. a cavity cut with a design to give its form or impression to some softer matter applied therein, of great use in sculpture, foundry, &c.

Mould, a thin flexible piece of timber, used by shipwrights as a pattern whereby to form the different curves of the timbers, and other compassing pieces in a ship's frame; of these there are two sorts, the bend-mould and the hollow-mould. The former of these determines the convexity of the timbers, and the latter the concavity on the outside, where they approach the keel, particularly towards the extremities of the vessel. The figure given to the timbers by this pattern is called the Beveling. See that article.

Moulds, in the manufacture of paper, are little frames composed of several brass or iron wires, fastened together by another wire still finer. Each mould is of the bigness of the sheet of paper to be made, and has a rim or ledge of wood to which the wires are fastened; these moulds are more usually called frames or forms.

Moulds for Lead *Bullets*, are little iron pincers, each of whose branches terminates in an hemispherical concavity, which when shut forms an entire sphere; in the lips or sides, where the branches meet, is a little jet or hole through which the melted lead is conveyed.

Moulds, Glaziers'. The glaziers have two kinds of moulds, both serving to cast their lead. In the one they cast the lead into long rods or canes fit to be drawn through the vice, and the grooves formed therein; this they sometimes call ingot mould. In the other they mould those little pieces of lead a line thick, and two lines broad, fastened to the iron bars; these may be also cast in the vice.

Moulds, among plumbers, are the tables whereon they cast the sheets of lead. These they sometimes call simple tables; besides which they have other real moulds wherewith they cast pipes without soldering.

Moulds, used in basket-making, are very simple, consisting ordinarily of a willow or osier, turned or bent into an oval, circle, square, or other figure, according to the baskets, panniers, hampers, hats, and other utensils intended.—On these moulds they make, or, more properly, measure all their work, and accordingly they have them of all sizes, shapes, &c.

Moulds, among tallow-chandlers, are of two kinds: the first for the common dipped candles, being the vessel wherein the melted tallow is disposed, and the wick dipped; this is of wood of a triangular form, and supported on one of its angles, so that it has an opening of near a foot at top: the other, used in the fabric of mould candles, is of brass, pewter, or tin; here each candle has its several moulds.

Mould, among gold-beaters, a certain number of leaves of vellum, or pieces of gut cut square, of a certain size, and laid over one another, between which they put the leaves of gold and silver, which they beat on the marble with the hammer. They have four kinds of moulds, two whereof are of vellum, and two of gut; the smallest of those of vellum consists of forty or fifty leaves, the largest contains an hundred; for the others, each contains five hundred leaves. The moulds have all their several cases, consisting of two pieces of parchment, serving to keep the leaves of the mould in their place, and prevent their being disordered in beating.

Mould, in Agriculture, a loose kind of earth every where obvious on the surface of the ground; called also natural or mother earth; by some also, loam.

MOULDINESS, a term applied to bodies which corrupt in the air, from some hidden principle of humidity therein, and whose corruption shews itself by a certain white down, or lanugo, on their surface, which viewed through a microscope appears like a kind of meadow, out of which arise herbs and flowers, some only in the bud, others full blown, and others decayed, each having its root, stalk, and other part. See *Mycor*.

MOULDING, any thing cast in a mould, or that seems to have been so, though in reality it were cut with the chisel or the axe.

MOULDINGS, in Architecture, projections beyond the naked wall, column, wainscot, &c.

MOUNTAIN BLUE. The substance called mountain blue, is one of the native varieties of carbonate of copper, of which

there are three, the green, the blue, and the anhydrous. The following is the order of their compositions:—

	1st.	2d.	3d.
Carbonic acid	2.75	11.00	2.57
Deutoxide of copper	10.00	30.00	10.00
Water	1.125	2.25	0.00

The blue carbonate is found in great perfection at Chessy, near Lyons; also in Bohemia, Saxony, &c. It occurs crystallized, in rhomboids, and imperfect octohedra. It also is found in small globular masses, massive and earthy. The earthy variety is called copper azure or mountain blue. The green variety is called malachite, it is found in various forms, but never regularly crystallized, the octohedral variety being a pseudo-crystal derived from the decomposition of the red oxide. This mineral occurs in the greatest beauty in the Uralian mountains of Siberia: it is rarely found in Cornwall. It is of various shades of green, and often cut into small slabs, or used as beads and brooch-stones; the pulverulent variety has been termed chrysocollæ and mountain green. There is a very fine blue cupreous preparation called refiner's verditer, principally made by silver refiners. It consists of three proportions of oxid, four of carbonic acid, and two of water. There is a very inferior pigment, also called verditer, which is a mixture of sub-sulphate of copper and chalk. According to Pelletier, a good verditer may be obtained as follows: Add a sufficient quantity of lime to nitrate of copper, to throw down the hydrated oxide; it gives a greenish precipitate, which is to be washed and nearly dried upon a strainer; then incorporate with it from eight to ten per cent. of fresh lime, which will give it a blue colour, and dry it carefully. Proust obtained a fine blue carbonate of copper, by adding an alkaline carbonate to a solution of nitrate of copper. The artificial carbonates will probably not answer with every experimentalist. If not, the native mountain blue may possibly be obtained either under that name or copper azure.

MOUNTAINS. Elevations consisting of clay, sand, or gravel, are called hills; those which consist of stone are called mountains. Mountains are divided into primæval, that is, of equal date with the formation of the globe, and secondary or alluvial. Among primæval, those of granite hold the first place. The highest mountains and most extensive ridges throughout the globe are of that kind. The highest of them never contain metallic ores; but some of the lower contain ores of copper and tin. The granite next the ore always abounds in mica. Petrifications are never found in these primæval mountains. That the formation of these mountains preceded that of vegetables and animals, is inferred from their containing no organic remains, either in the form of petrification or impression. Granites were formed by crystallization, an operation that probably took place after the formation of the atmosphere, and the gradual excavation of the bed of the ocean, when the dry land appeared. For by means of the separation of the æriform fluids which constitute the atmosphere, the evaporation of part of the water into the atmosphere, and the gradual retreat of the remainder, the various species of earths, before dissolved or diffused through this mighty mass, were disposed to coalesce; and among these the siliceous must have been the first, as it is the least soluble; but as the siliceous earth has an affinity to the other earths with which it was mixed, some of these must have united in various proportions, and thus have formed in distinct masses, the feldspar, schorl, and mica, which compose the granite.

Calcareous earth enters sparingly into the composition of this stone; but as it is found in schorl, which is frequently a component part of granite, it follows that it must be one of the primitive earths, and not entirely derived from marine exuvie. Quartz cannot be a product of fire; for in a very low heat it bursts, cracks, and loses its transparency, and in the highest degree of heat that we can produce, it is infusible, so that in every essential point it is different from glass. As granite contains earth of every genus, we may conclude that all the simple earths are original. Mountains which consist of limestone or marble of a granular or scaly texture, and not disposed in strata, seem also to have preceded the creation of animals, for no organic traces are found in them. Some of those which con-

most of argillaceous stones, and some of the siliceous, contain also no organic remains.

MOUNTAINS are evidently of posterior formation, as they contain petrifications and other vestiges of organic substances, and these are always stratified. Mountains, as to structure, are entire, stratified, and confused. Entire mountains are formed of huge masses of stone, without any regular fissures, and are mostly homogeneous. Stratified mountains are those whose mass is regularly divided by joints or fissures, these are called horizontal, rising, or dipping. Homogeneous stratified mountains consist chiefly of stones of the argillaceous genus, or of the fissile compound species of the siliceous genus, as metallic rock; sometimes of limestone of a granular or scaly texture, in which no animal vestiges appear. This limestone reposes on the argillaceous or siliceous strata; sometimes the argillaceous are covered with masses of granite, sometimes of lava. These mountains, particularly those of gneiss, metallic rock, and horn-stone, are the chief seat of metallic ores. Heterogeneous, or compound stratified mountains, consist of alternate strata of various species of stones, earths, sands, &c. The limestone here is always of the laminar, and not of the granular or scaly kind, and when it contains any ore, it is placed between its laminae. Coal, bitumen, petrifications, and organic impressions, are found in these mountains; also salts and calamine. There are other mountains which cannot be called stratified, as they consist only of three masses: the lowest granite, the middle argillaceous, and the upper limestone. Metallic ores are found in the argillaceous part, or between it and the limestone. Confused mountains consist of stones heaped together without order, their interstices being filled with clay, sand, and mica. They scarcely ever contain any ore. Besides these, there are many mountains in different parts of the world, which derive their origin from volcanoes. The height of mountains is usually calculated by means of the barometer. See **BAROMETER**. The highest mountains are those which are situated at or near the equator. The Himalaya and the Andes are generally allowed to be the highest of these, the line of congelation, or of perpetual frost on mountains, is calculated at 15,400 feet, at or near the equator; at the entrance of the temperate zone, at 13,428; at Teneriffe, at 1060; in Auvergne (lat. 45) 6,740; with us (lat. 52), 5,740. On the Andes, vegetation ceases at 14,497 feet; and on the Alps at 9,565. The air is so dry in these elevated situations, that M. d'Arcet observed, that on the Pic de Midi, one of the Pyrenees, salt of tartar remained dry for an hour and a half, though it immediately warmed in the same temperature at the bottom of the mountain.

MOUNTING, in Military affairs, signifies going upon duty. Thus, mounting a breach is running up to it; mounting the guard, is going upon guard; and mounting the trenches, is going upon duty in the trenches; but mounting a cannon, mortar, &c. is the setting it on its carriage, or the raising its mouth.

MOUSE, a sort of knob, wrought on the outside of a rope by means of spun-yarn, parsling, &c. See the article **PUDENING**. It is particularly used on the stays, to prevent it from unhooking when the tackle is slackened.

MOUSE. See **MUS**.

MOVEABLE, in general, denotes any thing capable of being moved. The moveable feasts are such as are not regularly held on the same day of the year or month, though they are always on the same day of the week. Thus Easter, on which all the rest depend, is held on the Sunday which falls upon, or next after, the first full moon following the 21st of March.

MOVEMENT, in Mechanics, a machine that is moved by clock-work. See **CLOCK**.

MOVEMENT, in Military affairs. Under this term are comprehended all the different evolutions, marches, countermarches, and manœuvres, which are made in tactics for the purpose of retreating from, or of approaching towards, an enemy. It also includes the various dispositions which take place in pitching a camp, or arranging a line of battle.

MOVEMENT, in Music, the name given to any single strain, or to any part of a composition comprehended under the same measure of time.

MUCIC ACID, was called sacclactic acid from its having been found in the sugar of milk; but as oxalic acid is also

found in milk, and this acid is found in all gums, it has been better distinguished by the name of mucic. It forms, with the oxides of metals, salts which are scarcely soluble.

MUCILAGE, a glutinous matter obtained from vegetables, transparent and tasteless, soluble in water, but not in spirits of wine. It chiefly consists of carbon, hydrogen, and a small quantity of oxygen. See **GLUTEN**.

MUCOR, in Botany, a genus of the order fungi, in the cryptogamia class of plants. There are seventeen British species. The lichnoides, or little, black, pin-headed mucor, grows in groups near to each other, in chasms of the barks of old trees, and upon old park-pales. The common gray mould, grows on bread, fruit, plants, and other substances in a putrid state. It grows in clusters: the stalks a quarter of an inch high, pellucid, hollow, and cylindrical, supporting each in a single globular head, at first transparent, afterwards dark-gray; which bursts with elastic force, and ejects small round seeds discoverable by the microscope. The yellow frothy mucor, is found on the leaves of plants, such as ivy, beech, &c. sometimes upon dry sticks, and frequently upon the tan or bark in hot-houses. It is of no certain size or figure, but of a fine yellow colour, and a substance at first resembling cream beaten up into froth. In the space of 24 hours it acquires a thin filmy coat, becomes dry, and full of sooty powder adhering to downy threads.

MUCUS, a fluid secreted by certain glands, and serving to lubricate many of the internal cavities of the body. In its natural state it is generally limpid and colourless; but from certain causes will often assume a thick consistence, and whitish colour, like pus; but strong sulphuric acid and water, diluted sulphuric acid, and caustic alkaline, lixivium, and water, will serve to distinguish pus from mucus; the vitriolic acid separates it from coagulable lymph, and alkaline lixivium from serum. Thus when a person expectorates matter, the decomposition of which he wishes to ascertain, let him dissolve it in vitriolic acid, and in caustic alkaline lixivium; and let him add pure water to both solutions. If there is a fair precipitation in each, he may be assured that some pus is present. But if there is a precipitation in neither, it is a certain test that the mixture is entirely mucus. If the matter cannot be made to dissolve in alkaline lixivium by time and trituration, we have also reason to believe that it is pus.

MUCUS, NASAL, a name given to a liquid secreted in the cavities of the nose, and discharged outwardly, either by the nostrils or by the fauces when it descends by the posterior part of the nasal cavities, in which it is thrown out by spitting. This liquid, always exposed to the air, which continually passes through the nostrils, is thicker, more viscid, and more adhesive than the tears; and the carbonate of soda it contains, whilst the latter contains only soda, announces that the air deposits in it a part of the carbonic acid which it contains, especially as it is expired out of the lungs. When it becomes thick in the air, it frequently assumes in it the form of small, dry, brilliant, and as it were micaceous plates. The nasal mucus experiences no real putrefaction in the air. Water does not dissolve it. Acids thicken it when they are concentrated and employed in small proportions; but when we add a larger quantity, they re-dissolve, and give it different shades of colour. The mucus of the nostrils maintains the softness of the membranaceous sides of the nasal cavities. It moderates the too great sensibility of the nervous papillæ, stops and fixes the odorous bodies, and blunts their too great activity. It likewise purifies the air that is respired, by taking from it the pulverulent particles which it carries along with it, and which would be more hurtful in the lungs.

MUFFLE, in metallurgy, an arched cover, resisting the strongest fire, and made to be placed over coppels and tests in the operations of assaying, to preserve them from the falling of coals and ashes into them; though, at the same time, of such a form, as is no hindrance to the action of the air and fire on the metal, nor to the inspection of the assayer.

To **MUFFLE the Oars**, is to put some matting, &c. round that part of the oar which lies on the edge or gunnel of the boat, when rowing, to prevent its making a noise against the tholes.

MUFTI, or **MUPHTI**, the chief of the ecclesiastical order, or primate, of the Mussulman religion. His authority is very great.

In all actions, especially criminal ones, his opinion is required by giving him a writing, in which the case is stated under feigned names, which he subscribes with words, *He shall or shall not be punished*. Such outward honour is paid to the mufti, that the grand seignior himself rises up to him, and advances seven steps to meet him, when he comes into his presence. The election of the mufti is solely in the grand seignior.

MUGIL, MULLET, a genus of fishes of the order abdominales. Gmelin notices only five species. Shaw mentions nine. The common mullet is generally about 14 inches in length, and is found not only in the Northern and Mediterranean seas, but in the Indian and Western oceans. The mullets collect in multitudes almost close to the shores, thrusting their head into the soft muddy bottoms in quest of aquatic insects. On the approach of summer they ascend rivers to a considerable distance from the sea, to deposit their ova. They are regarded by many as excellent food, but are not often seen at the tables of the opulent.

MULBERRY. See **MORUS**.

MULE, in zoology, a mongrel kind of quadruped, generated between an ass and a mare, and sometimes between a horse and a she-ass. The mule is a monster of a middle nature between its parents, and incapable of propagating its species. Mules are chiefly used in countries where there are rocky and stony roads, as about the Alps, Pyrenees, &c. No creatures are so proper for carrying large burdens, and none so sure footed. They will travel several months together with six or eight hundred weight upon their backs; they are much harder and stronger than the horse, and will live and work twice his age.

MULES, among gardeners, denote a sort of vegetable monsters produced by putting the farina fecundans of one species of plant into the pistil or utricle of another. The signification of the word is likewise extended to every kind of animal produced by a mixture of two different species.

MULLERS FOR GRINDING COLOURS, according to the common construction, are too well known and too simple to need a particular description here. But Rawlinson's *concave muller*, for which the Society of Arts presented him a silver medal and ten guineas, on account of its ingenuity, shall find a place here.—This machine has been used for several years, and has been found much more effectual and expeditious in reducing the colour to extreme fineness than the usual method, and much less injurious to the health of the workman, who frequently has done as much with it in three hours as he could in twelve with the muller and slab. The machine consists of a flat cylinder of black marble, sixteen inches and a half diameter, and four and a half thickness, with an axle traversing its centre, (thus somewhat resembling a common cutler's grindstone.) It is suspended on a similar frame, in a vertical position, and turned round in the same manner by a winch: a concave piece of marble is provided, of the same breadth as the circular stone, forming a segment of the same circle one-third of the circumference in extent: this, which may be considered as the muller, is fitted into a piece of solid wood of similar shape, one end of which is secured loosely by a hinge or otherwise to the frame; the other end, rising over the circular stone, and supported by it, is further pressed down on it by a long spring bent over from the opposite extremity of the stand, and regulated as to its pressure by a screw, whose end turns against the concave muller: a slight frame of iron in front, moveable on a hinge, by which it is secured to the frame, supports a scraper, for taking off the colour, formed of a piece of watch-spring, which is turned back out of the way when not in use. Mr. R. thinks the circular grindstones might be made much larger than he used, to advantage, and that one of two feet diameter would not occasion too much labour to one man to turn it: he computes that in his machine there are seventy square inches of surface of the concave muller in constant work on the paint, while in the common muller not more than sixteen square inches are usually in contact with the slab. The machine will be found equally serviceable for the colours ground in water as for those prepared with oil, according to Mr. R., who highly recommends its use to all colourmen. Mr. R. advises, in making up the colours in bladders, to insert a bit of quill or reed in the neck of the bladder, which will thus bind

better in tying; and, admitting of a secure stopper, will be more cleanly and less wasteful than the usual method of stopping with a nail, and keep the colour more safe from the air.

MULLUS, SURMULLET, a genus of fishes of the order thoracici. Gmelin reckons six, Shaw thirteen species. The red surmullet is principally found in the Mediterranean and North seas, where it arrives at the length of twelve or fifteen inches; its colour is a rose red, tinged with olive-colour on the back, and of a silvery cast towards the abdomen. It is generally considered as a very delicate fish, and is celebrated for having been the fashionable object of Roman luxury, and for which enormous sums are reported to have been sometimes given. The Romans practised a singular refinement in luxury, by first bringing the fish alive to the table, in a transparent vessel, in order that the guests might contemplate the beautiful and rapid changes of its evanescent colours during the time of its gradual expiration; after which, it was prepared for their repast.

MULTANGULAR, a figure, or body, which has many angles.

MULTILATERAL, in Geometry, is applied to figures which have more than four sides or angles.

MULTINOMIAL, or **MULTINOMIAL ROOTS**, in Mathematics, such roots as are composed of many names, parts, or members: as, $a + b + d + e$, &c. See **ROOT**.

MULTIPLE, in Arithmetic, is a number which contains another number a certain number of times; thus 18 is a multiple of 6, or of 3, or of 9, &c.

Common MULTIPLE of two or more numbers, is that which contains those numbers a certain number of times; thus 36 is a common multiple of 4 and 9, being equal to 9 times the first, and 4 times the second.

To find the least common Multiple of several Numbers.—Reduce them all to their prime factors, then the product of the greatest powers of those prime factors is the least common multiple required. Let it be proposed to find the least common multiple of 12, 25, and 35, or the least number that will divide by each of them without a remainder.

Here $12 = 3 \times 2^2$; $25 = 5^2$, and $35 = 5 \times 7$; therefore $3 \times 2^2 \times 5^2 \times 7 = 210$, the least common multiple required.

MULTIPLE RATIO, or *Proportion*, is that which is between multiples. If the less term of the ratio is an aliquot part of the greater, the ratio, or the greater to the less, is called the multiple, and that of the less to the greater, submultiple. A submultiple number is that contained in the multiple; thus, the numbers 1, 2, and 3, are submultiples of 9. Duple, triple, &c. ratios, as also sub-duples, sub-triples, &c. are so many species of multiple and submultiple ratios.

MULTIPLICAND, in Arithmetic, is one of the factors in multiplication, being that which is multiplied by the other, which is called the multiplier.

MULTIPLICATION, is one of the principal rules in arithmetic and algebra; and consists in finding the amount of a given number or quantity, called the multiplicand, when repeated a certain number of times expressed by the multiplier; and this amount is generally termed the product; also the multiplier and multiplicand are commonly called factors. Multiplication is either simple or compound.

Simple MULTIPLICATION, is when the proposed quantities are integral numbers.—*Rule.* Place the multiplier under the multiplicand, so that units may fall under units, tens under tens, and so on. Then begin at the right hand, and multiply every figure in the multiplicand, by each of the figures in the multiplier. Find how many tens there are in the product of every two simple figures, and set down the remainder directly under the figure you are multiplying by, or, if there be nothing over, a cipher. Carry as many units as there were tens to the product of the next figure, and proceed in like manner till the whole is finished. Then add all the separate products together for the answer.

Proof of MULTIPLICATION. 1. Invert the operation, by making the multiplier and multiplicand change places, and if you thus obtain the same result, it is highly probable the work is right. 2. Cast out all the 9's from the multiplier, multiplicand, and product; and multiply the overplus of the two former together, and cast the 9's out of this product: then if

this remainder be the same as that arising from the total product, the operation is probably right; but if not, it is certainly wrong. This proof depends upon a singular property of the number 9; viz. that any number divided by 9, will leave the same remainder, as the sum of its digits when divided by the same number. 3. Another proof for multiplication is drawn from a particular property of the number 11, which is this, that the sum of the digits in the odd places, that is, the 1st, 3d, 5th, &c. being taken from the sum of the digits in the 2d, 4th, &c. places, the remainder, when divided by 11, will leave the same overplus, as the whole number when divided by 11. If the former sum be greater than the latter, as many times 11 must be added to it, as will make the latter sum the greater of the two. This being observed, the proof by this number will be the same as in the former case.

Example.

45684 multiplicand.
4374 multiplier.

209821816

$\begin{array}{r} \times 9 \\ 45684 \\ \hline \end{array}$ proof by 9.

$\begin{array}{r} \times 11 \\ 45684 \\ \hline \end{array}$ proof by 11.

But it must be evident that this process is at variance with all the known laws of mathematical science, since it supposes a knowledge of division even previous to that of multiplication, which is absurd; and the editor very reluctantly admits into the pages of his work an illustration which is opposed to practice, but sanctioned by the authority of a custom known only among the unscientific and illiterate.

The other proof by inverting the operation depends upon this; that the product of two numbers is the same, whichever of the two is the multiplier; or generally, that a times b is the same as b times a ; which, though generally considered as an axiom, is in fact a proposition, and one that is not very easily demonstrated.

Compound MULTIPLICATION, is the method of finding the product arising from a compound and simple quantity.—*Rule.* Place the multiplier under the lowest denomination of the multiplicand, and multiply this denomination by the multiplier. Find how many units of the next higher denomination are contained in the product; set down the remainder, and carry the units to the next product, with which proceed as before, and so on through all the denominations to the last, and the result will be the answer required.

Note. If the multiplier exceed 12, the operation will be much simplified as follows:—1. If the given multiplier be a composite number, multiply successively by each of its factors, instead of the whole number at once. 2. If the given multiplier be not a composite number, take that which is nearest to it, and multiply by its factors as before; then add or subtract as many times the first line, as the number so taken is less or greater than the multiplier. Also, if there be any fractional part belonging to the multiplier, take such part of the multiplicand as this fraction is of a unit, and add it to the result before found.

MULTIPLIER, or **MULTIPLICATOR**, the number by which another is multiplied.

MULTIPLYING GLASS, in Optics, one wherein objects appear increased in number. It is otherwise called a polyhedron, being ground into several planes that make angles with each other; through which the rays of light issuing from the same point undergo different refractions, so as to enter the eye from every surface in a different direction.

MULTIVALVES, in Natural History, the name of a general class of shell-fish consisting of three or more shells.

MUM, a kind of malt liquor much drunk in Germany, and chiefly brought from Brunswick, which is the place of most note for making it.

MUMMY, a body embalmed or dried, in the manner used by the ancient Egyptians: or the composition with which it is embalmed. Mummy has been esteemed resolvent and balsamic; but whatever virtues have been attributed to it, seem to be such as depend more upon the ingredients used in preparing the flesh than in the flesh itself.

MUNICIPAL, in the Roman civil law, an epithet which signifies invested with the rights and privileges of Roman citizens.

MUNICIPAL, in Great Britain, is applied to the laws that obtain in any particular city or province; and those are called

municipal officers who are elected to defend the interest of cities, to maintain their rights and privileges, and to preserve order among the citizens.

MURAL ARCH, (from *murus*, a wall,) a wall, or arched wall, placed exactly in the plane of the meridian, for fixing a large quadrant, sextant, or other instrument, to observe the meridian altitude, &c. of the heavenly bodies.

MURÆNA, the *Eel*, a genus of fishes of the order apodes. There are five species, according to Shaw. Gmelin enumerates nine. The common eel is particularly distinguished by the steadiness and uniformity of its colours; an olive-brown on the back, and silvery lustre on the sides and beneath; but more expressively still by the great elongation of its under jaw. Its general size is from two to three feet; it is slow in its growth, and considered as very long lived. Its usual food consists of insects, worms, and the eggs of other fishes. It is viviparous, producing great numbers at a birth; but of a very diminutive size. It continues generally during the day in its hole in the banks, which it furnishes with two avenues, to facilitate its escape and security. By night it ranges for food. In winter it appears to be engulfed in mud, and remains in this state of seclusion and tranquillity, if not torpor, till the return of spring invites it to a renewal of its excursions. The conger eel, generally darker above, and more splendid beneath than the former species, grows to its largest size in the Mediterranean, where it is sometimes found ten feet long, and a hundred pounds weight. It is found in the North American seas also: it occasionally, particularly in the spring, makes excursions into rivers, and is found in vast abundance in the Severn. Congers are extremely voracious, devouring immense quantities of the smaller fishes, and of crabs before the shell of the latter is completely formed and hardened.

MURDER. See **HOMICIDE**.

MUREX, in Natural History, a genus of univalve or simple shells, without any hinge, formed of a single piece, and beset with tubercles or spines. The mouth is large and oblong, and has an expanded lip, and the clavicle is rough.

MUREX, in Zoology, a genus of insects belonging to the order of vermes testacea. From a species of murex on the coasts of Guayaquil and Guatemala, in Peru, a liquor is extracted which dyes cottons, silks, and wool of a beautiful permanent purple colour. The shell which contains it adheres to the rocks that are washed by the sea. It is of the size of a large walnut. The liquor may be extracted two ways; some kill the animal after they have drawn it out of the shell, then press it with a knife from head to tail, separate from the body the part where the liquor is collected, and throw away the rest. When this operation, after being repeated on several snails, has afforded a certain quantity of fluid, the thread intended to be dyed is dipped in it, and the process is finished. The colour, which is at first of the whiteness of milk, becomes afterwards green, and is not purple till the thread is dry. Those who disapprove of this method draw the fish partly out of the shell, and, squeezing it, make it yield a fluid which serves for dyeing: they repeat this operation four times at different intervals, but always with less success. If they continue it, the fish dies. No colour at present known, says the Abbe Raynal, can be compared to this, either as to lustre, liveliness, or duration. It succeeds better on cotton than wool, linen, or silk.

MURIATES, in Chemistry, a genus of salts formed from the muriatic acid with certain bases.

MURIATIC ACID. When equal volumes of hydrogen and chlorine gases are mixed and exposed to light, they combine and produce a sour compound commonly called muriatic acid gas, or, in conformity to the modern nomenclature, hydrochloric acid gas. Muriatic acid may also readily be procured by acting upon common salt by sulphuric acid; the evolved gas must be received over mercury. It was first obtained pure by Dr. Priestley, but its composition was discovered by Scheele, and has since been most ably investigated by Sir Humphrey Davy. Muriatic acid gas extinguishes flame: it is greedily absorbed by water, which takes up 480 times its bulk, and has its specific gravity increased from 1 to 1.210. Thus, dissolved in water, it forms the liquid muriatic acid, or spirit of salt, and may easily be procured by distilling a mixture of dilute sulphuric acid and common salt, as directed in the Lon-

don Pharmacopœia. The marine acid in commerce has a straw colour; but this is owing to accidental impurity; for it does not obtain in the acid produced by the impregnation of water with the acériform acid. The muriatic acid is one of those longest known, and some of its compounds are among those salts with which we are most familiar. The muriates, when in a state of dryness, are actually chlorides, consisting of chlorine and the metal; but moisture makes them instantly pass to the state of muriates.

MURRAIN, or **GARGLE**, a contagious disease among cattle, principally caused by a hot dry season, or general putrefaction of the air, which begets an inflammation of the blood, and a swelling in the throat, that soon proves mortal. The symptoms are, a hanging down and swelling of the head, abundance of gum in the eyes, rattling in the throat, a short breath, palpitation of the heart, staggering, a hot breath, and a shining tongue.

MUS, the *Rat*, a genus of mammalia, of the order glires. There are forty-six species. The musk rat, as large as a small rabbit, and very common in Canada, resembles the beaver in the shape of its body, and in its instincts and character. It lives in society, and constructs its habitation with great skill and art, about two feet in diameter, and stuccoed within with particular neatness, on the border of some lake or stream. On the outside it is covered with a matting of rushes, compacted with great closeness to preclude moisture. These animals live on roots and herbage, which, however, they do not store up in their houses, but make excursions for, as they are wanted during the winter; in summer they make long progresses in pairs. They have a strong odour of musk, and walk and run with great awkwardness; are easily tamed, and highly valued for their fur. The Norway rat, supposed to have been imported into Europe from India, has in this country almost extirpated the black rats. It subsists not only on grain and fruits, but frequently attacks poultry and rabbits, as well as various other animals. The black rat, is considerably smaller than the former; its habits are almost precisely similar. It is supposed to come from the same countries. It is reported by travellers, that in various parts of Germany it is sometimes taken and domesticated, and, having a bell put round its neck, is thus almost invariably found to alarm all others of its species from the vicinity. The water rat, inhabits the temperate and cold climates of Europe and Asia, frequenting the banks of rivers in which it burrows. It subsists on frogs, on roots and other vegetable substances; swims with great speed, and can remain under water a considerable time. It never infests houses. The hamster, is a species of the pouched rats, and the sole European species of that description. The pouches are one on each side of the mouth, and, when filled, are like two blown bladders. These animals are found in Poland and Russia, and are extremely injurious by the quantities of grain which they devour, and carry off for their autumnal store in their pouches. The females arrange their mansions differently from the males, and never reside with them. As winter approaches, they seclude themselves completely, and enjoy their stores, which are generally consumed when the winter reigns in full rigour: they roll themselves up, and continue till spring in a state of profound slumber. Their bodies are cold, the fat coagulated, and their limbs stiffened, and they may be opened without awaking them. The heart beats only fifteen times in a minute, while in the summer its pulsations are 150 in the same time. The waking of the hamsters from their lengthened sleep is gradual, occupying sometimes no less than two hours. These animals are unsocial, fierce, and malignant. They attack every weaker creature, and very frequently destroy each other. The common mouse, inhabits almost every part of the world, is shy and timid, but not ferocious. It produces generally from six to ten at a birth, and breeds several times in a year. Its skin is sleek, and its eyes are bright and lively; its limbs are neatly formed, and its movements are extremely agile. The long-tailed field-mouse, is somewhat larger than the former, and of a yellowish-brown colour. It feeds on acorns, fruits, and grain, and lays up magazines in its burrow for the winter. It is found principally in dry grounds, is common in all the temperate regions of Europe, and is particularly abundant and destructive in France, where it is stated to commit very great waste. Under a scarcity of the usual supplies, these animals are sup-

posed to destroy each other. The harvest mouse, is the smallest of British quadrupeds, weighing only the sixth part of an ounce. Its nest is most artificially platted of the blades of wheat, and of the size of a cricket ball, the opening to it being closed up so skilfully, as to be almost imperceptible. Such is its compactness, that it may be rolled over the table without derangement. One found of this description contained eight young, and appeared completely full without the dam. In the winter these animals burrow deep in the earth; but their favourite habitation is the corn-stack. The blind rat, is perhaps one of the largest and most remarkable of its tribe, measuring between seven and eight inches in length, and being entirely destitute both of eyes and tail.

MUSA, in Botany, a genus of the polygamia monoecia class and order. Natural order of scitamineæ. There are three species: *M. paradisiaca*, plantain-tree, rises with a soft herbaceous stalk, fifteen or twenty feet in height; the lower part of the stock is frequently as large as a man's thigh, diminishing gradually to the top, where the leaves come out on every side, being often more than six feet long and two broad. When the plant is grown to its full height, the spike of flowers appears from the centre of the leaves nearly four feet in length, nodding on one side. The fruit is about nine inches long, and more than an inch in diameter, a little incurved, having three angles; the skin is tough, within is a soft pulp of a luscious sweet flavour; the spikes of the fruit are often so large as to weigh upwards of forty pounds. It is a native of the East Indies and other parts of the Asiatic continent; it is generally cultivated between the tropics, the fruit being excellent nutritious food. The banana-tree, differs from the preceding in having its stalks marked with dark purple stripes and spots: the fruit is shorter and rounder, with a soft pulp of a more luscious taste. See **BANANA**.

MUSCA, in Natural History, the *Fly*, a genus of insects of the order diptera. This is a very numerous genus, not fewer than a thousand species having been enumerated. They are divided into sections; viz., A. with short feelers; and B. without feelers. These sections are again separated into others. The larva in the different tribes of flies differ far more in habit than the complete insects, some being terrestrial, and others aquatic. Those of the common kinds are distinguished by the title of maggots, and spring from eggs deposited on various putrid substances. Several of the aquatic kinds are of singularly curious formation, and exhibit wonderful examples of the provision ordained by nature for the preservation of even the meanest animals. The general form of the pupa is that of an oval, differently modified, according to the species, and formed by the external skin of the larva. Some species cast their skin before they change into the pupa state.

MUSCA AUSTRALIS, the *Southern Fly*, or *Bee*, is situated south of the Cross, and by the Antarctic circle; it contains four stars of the fourth magnitude. The introduction of the *Bee* among the celestial host is a pretty idea, as well on account of the natural qualities of this most extraordinary insect, as on account of its being the old hieroglyphic of royalty. Of the insentient part of animated nature, the bee is prince and chief for foresight, ingenuity, industry, and fidelity: it was thence the fittest symbol of a good king.

MUSCA BOREALIS, the *Northern Fly*, is a small and modern asterism, containing only six stars, viz. one of the third magnitude, two of the fourth, &c. It is situated north of Aries, and south of Triangula and Perseus.

MUSCHENBROEK, **PETER**, a very eminent mathematician and philosopher, was born at Utrecht, about the year 1700. He was professor of mathematics, first in that city, and afterwards at Leyden, where he died in 1761.

MUSCI, in Botany, *Mosses*, one of the seven families into which Linnæus divided all vegetables. These plants constitute the second order of the class cryptogamia. This order is subdivided into eleven genera, from the presence or absence of the calyx, which in these plants is a veil that is placed over the tops of the stamina, and denominated calyptra, from the sexes of the plants, which bear male and female flowers, sometimes on the same, sometimes on distinct roots, and from the manner of growth of the female flowers, which are sometimes produced singly, sometimes in bunches or cones.

MUSCI, is also the name of the fifty-sixth order in Linnaeus's *Fragments of a Natural Method*, consisting of genera which are exactly those of the second order in the class cryptogamia. These plants resemble the pines and firs, and other evergreens in that class, in the form and disposition of their leaves, and manner and growth of the female flowers, which are generally formed into a cone. They frequently creep, and extend themselves like a carpet upon the ground, trees, and stones, collected into bunches or tufts. Few of the mosses are annual plants, being mostly perennial and evergreens. Their growth is slow; though preserved dry several years, they resume their original verdure upon being moistened. They delight in a cool moist situation, and northerly exposure, where they are screened from the sun. The roots are fibrous, slender, branched, and short. The stems and branches are cylindric and weak, creeping on the ground, and striking root on every side.

MUSCICAPA, the *Fly-catcher*, a genus of birds of the order *passeres*. There are seventy-nine species. The spotted fly-catcher arrives in this country in the spring, and leaves it in September. It attaches its nest not unfrequently to the end of a beam of a house; and sometimes builds it in a vine or sweet-briar tree, spread against a wall. It returns for a succession of seasons to the same situation. It feeds on insects, which it catches with astonishing dexterity, sometimes on the wing, sometimes by a sudden leap from its perch. It is one of the most silent and most familiar of summer birds. Its only note is a plaintive sound on the approach of danger. In Kent it is called the cherry-sucker, being particularly fond of that fruit. The pied fly-catcher, is not to be found in great numbers in any part of this island, but is most frequently to be met with in Yorkshire, and the contiguous counties.

MUSCLE, in Anatomy, a part of the human body, destined to move some other part, in general by a voluntary motion, being composed principally of flesh and tendinous fibres, with veins, nerves, and lymphatics; surrounded by, or enclosed in, one common membrane. The muscular parts of animals are known in common language by the name of flesh. Muscular flesh is composed of a great number of fibres and threads, of reddish or whitish colour; these, after they have been acted on by water, to separate the extraneous matter, are left in the state of gray fibres, insoluble in water, and becoming brittle when dry. The muscles likewise contain albumen, gelatine, extractive, phosphate of soda, of ammonia, and lime.

MUSCLES, *Insertion and Force of the*. The all-wise Author of nature has furnished animals with limbs moveable about the joints by means of muscular cords inserted near the joint, or centre of motion. In order to calculate the force of any muscle, we are to consider the bones as levers; and then the power or force of the muscle will be always to the resistance or weight it is capable of raising, as the greater distance of the weight from the centre of motion is to the lesser distance of the power. The muscles that move the lower jaw, when taken altogether, do not in a man exceed the weight of one pound, and yet exert a force equal to 534 pounds, and in mastiff-dogs, wolves, bears, lions, &c. their force is vastly superior. The motion of the far greater part of the muscles are voluntary, or dependent on our will; those of a few others involuntary. The former are called animal, the other natural motions. Finally, the motions of some of the muscles are of a mixed kind, partly animal and partly natural. Those muscles which perform the voluntary motions, receive nerves from the brain or spinal marrow; those which perform their motions involuntarily, have their nerves from the cerebellum; and those whose motion is partly voluntary, and partly involuntary, have theirs in part from the brain, and in part from the cerebellum.

MUSES, certain fabulous divinities amongst the Pagans, supposed to preside over the arts and sciences. Some reckon the muses to be no more than three, viz., Mneme, Aocde, and Melete; that is, Memory, Singing, and Meditation: but the most ancient authors, and particularly Homer and Hesiod, reckon nine; viz., Clio, which means glory; Euterpe, pleasing; Thalia, flourishing; Melpomene, attracting; Terpsichore, rejoicing the heart; Erato, the amiable; Polyhymnia, a multitude of songs; Urania, the heavenly; and Calliope, sweetness of voice. To Clio they attributed the invention of history; to Melpomene, tragedy; to Thalia, comedy; to Euterpe, the use

of the flute; to Terpsichore, the harp; and to Erato, the lyre and lute; to Calliope, heroic verse; to Urania, astrology; and to Polyhymnia, rhetoric.

MUSEUM, a collection of rare and interesting objects, selected from the whole circle of natural history and the arts, and deposited in apartments or buildings, either by the commendable generosity of rich individuals, generally governments or monarchs, for the inspection of the learned and the great mass of the public. The term, which means literally, a study, or place of retirement, is said to have been applied originally to that part of the royal palace at Alexandria appropriated for the use of learned men, and the reception of the literary works then extant. According to ancient writers, they were formed into classes or colleges, each of which had a competent sum assigned for their support; and we are further informed, that the establishment was founded by Ptolemy Philadelphus, who added a most extensive library.

MUSHROOM. *Agaricus Campestris*.—Is cultivated and well known at our tables for its fine taste and utility in sauces. These plants do not produce seeds that can be saved; they are therefore cultivated by collecting the spawn, which is found in old hot-beds and in meadow lands. Various methods have been lately devised for raising mushrooms artificially: but none seem to be equal to those raised in beds, as is described in all our books of gardening. Raising this vegetable in close rooms by fire heat, has been found to produce them with a bad flavour; and they are not considered so wholesome as those grown in the open air, or when that element is admitted at times freely to the beds.

MUSHROOM, *Brown*. *Agaricus Cinnamomeus*.—The whole of this plant has a nice smell, and when stewed or broiled has a pleasant flavour. It is to be found in dry woods, old pastures, &c. and is fit for use in October.

MUSHROOM, *Violet*. *Agaricus Violaceus*.—This mushroom requires more broiling than all the rest; but when done well and seasoned, it is very good. It is found in dry woods, old pastures, &c. where it grows to a large size.

MUSIC, a science, which teaches the properties, dependencies, and relations of melodious sounds; or the art of producing harmony and melody by the due combination and arrangement of those sounds. The ancient writers on this science differ greatly as to its object and extent. In general they give to it a much wider latitude than that which it obtains with us. Under the name of music they comprehended not only the melodious union of voices and instruments, but also the dance, gesture, poetry, and even all the other sciences. Hermes defines music to be the general knowledge of order; which was also the doctrine of Plato, who taught that every thing in the universe was music. Music, however, properly so called, only concerns the due order and proportion of sounds; and is divided into two parts, the theoretical and the practical. Theoretical music comprehends the knowledge of harmony and modulation; and the laws of that successive arrangement of sound by which air or melody is produced. Practical music is the art of bringing this knowledge and those laws into operation, by actually disposing of the sounds, both in combination and succession, so as to produce the desired effect; and this is the art of composition: but practical music may in fact be said to extend still further, and to include not only the production of melodious and harmonious composition, but also its performance.

MUSICAL or **HARMONIAL PROPORTION**. See **PROPORTION**.

MUSK, a substance secreted into a bag, situated in the umbilical region of the moschus moschifer. Its colour is brownish red; its feel unctuous; its taste bitter; and its smell aromatic and intensely strong. It is partially soluble in water, which acquires its smell; and in alcohol, but that liquid does not retain the odour of musk.

MUSKET, a fire-arm, borne on the shoulder, and used in war. The length of a musket is fixed at three feet eight inches from the muzzle to the pan. In Fortification, the length of the line of defence is limited by the ordinary distance of a musket-shot, which is about one hundred and twenty fathoms.

MUSKETON, a short thick musket, whose bore is the thirty-eighth part of its length: it carries five ounces of iron, or seven and a half of lead, with an equal quantity of powder.

MUSLIN, a fine thin sort of cotton cloth, which bears a downy nap on its surface. See COTTON.

MUSTARD, WHITE. *Sinapis Alba*.—This is sown early in the spring, to be eaten as salad with cress and other things of the like nature; it is of easy culture. A salad of this kind may be readily raised on a piece of thick woollen cloth, if the seeds are strewed thereon and kept damp; a convenient mode practised at sea on long voyages. Cress and rape may be raised in the same manner.

MUSTELA, a genus of quadrupeds of the order feræ. There are twenty-eight species. *M. lutra*, the common otter, found in almost every part of Europe, as well as in the colder regions of Asia; inhabiting the banks of rivers, and feeding principally on fish. The length of the otter is nearly two feet from nose to tail, and of the tail about 16 inches. Its colour is a deep brown, with a small light-coloured patch on each side of the nose, and another under the chin. The otter shews great sagacity in forming its habitation; it burrows under ground on the bank of some river or lake, and always makes the entrance of its hole under water, working upwards to the surface of the earth; and, before it reaches the top, makes several holts or lodges, that in case of high floods it may have a retreat, and then makes a minute orifice for the admission of air. The otter is naturally a very fierce animal, and will inflict very severe wounds on its antagonists. The female produces four or five young at a birth; this commonly happens early in the spring. Young otters, if taken at a very early age, may be tamed and taught to hunt for fish, and bring them to their master. The smaller otter, very much resembles the common otter, but is smaller: the body is of a dusky colour, but with a considerable cast of tawny. In size it falls short of the common otter, measuring about a foot in length. Its fur is very valuable, and next in beauty to that of the sable. The sea otter, is the largest of the otters, measuring about three feet from the nose to the tail, and the tail thirteen inches. The colour of this species is a deep glossy brownish black, the fur being extremely soft and very fine. Great numbers are found in Behring's islands, the Kamschatka, the Aleutian, Fox, and Kurile islands. The ferret, has eyes red and fiery. It inhabits Africa. In Europe it is tamed to catch rabbits, rats, &c. It procreates twice a year, and brings forth from six to eight at a time. The stoat, is about ten inches long, hair short, which in northern climates becomes white, except the outer half of the tail, which remains black. The fur is very valuable.

MUSTER, in a military sense, a review of troops under arms, to see if they be complete, and in good order; to take an account of their numbers, the condition they are in, viewing their arms and accoutrements, &c.

MUSTER Roll, a specific list of the officers and men in every regiment, troop, or company, which is delivered to the inspecting field-officer, muster-master, regimental or district paymaster (as the case may be) whereby they are paid, and their condition is known.

MUSTERING, the act of calling over a list of the whole ship's company, or any particular detachment thereof, who are accordingly to answer to their names.

MUTE, a person refusing to plead to an indictment for felony, &c. is considered as pleading guilty, and punished as upon confession. A prisoner deaf and dumb from his birth may be arraigned for a capital offence, if intelligence can be conveyed to him by signs or symbols.

MUTE, in Grammar, a letter which yields no sound without the addition of a vowel.

MUTILLA, genus of insects of the order hymenoptera.

MUTINEER, one who mutinies.

MUTINY, in a military sense, to mutiny is to rise against authority. Any officer or soldier who shall use traitorous or disrespectful words against the king, or any of the royal family; or who shall behave himself with contempt or disrespect towards the general, or other commander-in-chief of the forces, or shall speak words tending to their hurt or dishonour; or who shall begin, excite, cause, or join in any sedition; or who, being present at any mutiny or sedition, does not use his utmost endeavours to suppress the same, or, coming to the knowledge of any mutiny, or intended mutiny, does not give information to his commanding officer; or who shall strike his

superior officer, or draw, or offer to draw, or lift up any weapon or offer any violence against him, being in the execution of his office; or who shall disobey any lawful command of his superior officer, is guilty of mutiny.

MUTULE, in Architecture, a kind of square modillion, set under the cornice of the Doric order.

MYA, a genus of insects of the vermes testacea class and order. There are about twenty-five species. *M. declivis* has a brittle semi-transparent shell, sloping downwards near the open end; the hinge slightly prominent. It is found about the Hebrides, where the fish is in great esteem. *M. margaritifera*, is found in mountainous rivers, and about cataracts. It is about five inches long, and half as many broad; and it is noted for producing mother-of-pearl and pearls; the latter is said to be a disease of the fish analogous to the stone in the human body.

MYAGRUM, *Gold of Pleasure*, a genus of the tetradynamia siliculosa class and order. There are ten species. The sativum is cultivated in Germany for the sake of the expressed oil of the seeds.

MYCTERIA, the *Jabira*, a genus of birds of the order grallæ. The American jabira is nearly six feet in length. It abounds in the levels of Cayenne, and other parts of South America, feeds upon fish, of which it devours immense quantities, and builds in vast trees, laying only two eggs. It is extremely wild, and when young is used for food. *M. Asiatica* is likewise a very large bird, inhabits the East Indies, and feeds on snails.

MYOPES. Those who by a natural defect have the cornea and crystalline humour too convex, are called myopes. This figure, increasing the quantity of refraction, tends to render the rays of such pencils as are formed in the eye more convergent, so that the point where these same rays meet is on this side of the retina. Myopes see distinctly those objects only which are near, which send towards the eye rays more divergent, and thereby less disposed to converge, through the effect of refraction in the crystalline and other humours. This imperfection is remedied by the use of a glass slightly concave.

MYOXUS, the *Dormouse*, in Natural History, a genus of mammalia, of the order of glires, four grinders in each jaw; long whiskers, tail cylindric, bristly, and thicker towards the end; legs of equal length; fore feet with four toes. These animals feed only on vegetables, and burrow in the ground, in which they continue during the winter in a torpid state. They are nocturnal, sleeping in their habitations the greater part of the day; they carry food to their mouths with their fore paws, sitting erect; and advance by leaps of several feet at a time, instead of walking. There are four species. The fat dormouse, found in Germany and Russia, has much of the manners of a squirrel, haunting trees, and feeding on fruits and nuts, which it stores for its winter consumption. It was highly valued by the Romans as an article of food. It is six inches long to the tail, which is about four: it is not easily tamed. The common dormouse, nearly of the size of a mouse, and inhabits thick hedges, making its nest in the hollow of some tree, forms a hoard for the winter, during which it is for the greater part abstinent and torpid. It is occasionally roused by the intervention of temperate days, recurs to its stock, and then returns to its slumbers, till spring recovers it to daily exertion.

MYRIAD, the number ten thousand.

MYRISTICA, *Nutmeg Tree*, a genus of the dioecia syngenesia class and order. Natural order of lauri. There are three species, of which *M. aromatica*, aromatic or true nutmeg tree, grows to a considerable size in the East Indies. The leaves are aromatic; and if the trunk or branches be wounded, they will yield a glutinous red liquor.

MYRMECOPHAGA, the *Ant Eater*, a genus of mammalia, of the order bruta. They subsist on insects; thrusting their tongue into a nest of ants, the glutinous substance which exudes from it serves to attach to it inextricably numbers of them, and when the animal perceives that he has secured a sufficient number, he retracts his tongue, and swallows his victims. There are seven species.

MYRMELEON, *Lion Ant*, a genus of insects of the order

neuroptera. There are 16 species. The Myrmeleon in the larva state preys on ants and lesser insects; and for the purpose of ensnaring them sinks itself into the sand, and forms a kind of funnel or pit in which it lies buried, the head only appearing above the sand.

MYROXYLUM, a genus of the monogynia order, in the decandria class of plants. There is but one species, the peruvianum, a native of Peru, and the warmer parts of Africa. It is this shrub that yields the balsam of Peru, which is said to be extracted from it by coction in water. This balsam, as brought to us, is nearly of the consistence of thin honey, of a reddish-brown colour inclining to black, and an agreeable aromatic flavour.

MYRRH, a gum resin brought from the Levant and East Indies, and used in medicine. It is hard, dry, glossy, of a reddish brown colour, with an admixture of yellow: transparent or opaque; of a peculiar strong smell, and a bitter, somewhat biting taste. With water it forms a yellow opaque soluber, and by distillation yields an essential oil.

MYRTUS, *Myrtle*, a genus of the icosandria monogynia class and order. Nat. ord. hesperidæ. There are thirty-six species, and many varieties. This genus is composed of small

trees and shrubs; flowers in some solitary, with two scales at the base; in others, forming opposite corymbs or panicles, axillary or terminating. The common myrtle is a native of Asia, Africa, and the south of Europe. The allspice tree is about thirty feet in height, and two in circumference. It is a native of New Spain and the West Indies. The flavour and fruit have a highly aromatic fragrance.

MYTHOLOGY, the history of the fabulous gods and heroes of antiquity, with the explanations of the mysteries or allegories couched therein.

MYTILUS, the *Mussel*, a genus of insects of the vermes testacea class and order. There are between fifty and sixty species. *M. margaritiferus*, which inhabits the American and Indian seas, is about eight inches long, and something broader; the inside is beautifully polished, and produces true mother-of-pearl, and frequently the most valuable pearls. *M. edulis* inhabits European and Indian seas, found in large beds, adhering to the other bodies by means of a long silky beard: the fish affords a rich food, but is often noxious to the constitution.

MYXINE, the *Hag*, a genus of insects belonging to the order of vermes intestina.

N.

N A 1

NABOB is a title in the East Indies, which in its origin signified deputy, and was first assumed by subordinate governors, who ruled over districts under the soubah, or governor of a province. In the declension of the power of the Mogul, many of the nabobs obtained independent authority.

NACRE, or **MOTHER OF PEARL**, is the inner part of the shell of the pearl muscle. This is of a brilliant and beautifully white colour, and is usually separated from the external part by aqua-fortis, or the lapidary's mill. Pearl muscle shells are on this account an important article of traffic with China and many parts of India, as well as to the different countries of Europe. They are manufactured into beads, snuff-boxes, buttons, and spoons, fish and counters for card players, and innumerable other articles. The pearl muscles are not considered good as food; though after having been dried in the sun, they are sometimes eaten by the lower classes of people in the countries near which they are found.

NAILS, in Building, are small spikes of iron, brass, &c. for fastening pieces of wood together. Among the Hebrews, nails were anciently used for cancelling bonds, by striking them through the writing. The several sorts of nails are very numerous; as, 1. Back and bottom nails, with flat shanks to hold fast and not open the wood. 2. Clamp-nails for fastening the clamps in building, &c. 3. Clasp-nails, whose head clasping and sticking into the wood, render the work smooth, so as to admit a plane over it. 4. Clench-nails, used by boat and barge builders. 5. Clout-nails, used for nailing on clouts to axletrees. 6. Deck-nails. 7. Dog-nails, for fastening hinges on doors, &c. 8. Flat-points, much used in shipping, and are proper where there is occasion to draw and hold fast, and no convenience of clenching. 9. Jobent-nails, for nailing thin plates of iron to wood, &c. 10. Lead-nails, for nailing lead, leather, and canvass to hard wood. 11. Port-nails, for nailing hinges to the ports of ships. 12. Pound-nails, which are four square, used for paling. 13. Ribbing-nails, principally used in ship building, for fastening the ribs of ships in their places. 14. Rose-nails, which are drawn four square in the shank, and commonly in a round tool. 15. Rother-nails, which have a full head, and are chiefly used in fastening rother irons to ships. 16. Round-head nails, for fastening on hinges, or for any other use where a neat head is required. 17. Scupper-nails, which have a broad head, and are used for fastening lea-

ther and canvass to wood. 18. Sharp nails, with sharp points and flat shanks, for nailing soft wood. 19. Sheathing-nails. 20. Square-nails, used for hard wood, and nailing up wall-fruit. 21. Tacks, &c. Nails are said to be toughened when too brittle, by heating them in a fire shovel, and putting some tallow or grease among them.

The following table exhibits Mr. Bevoir's experiments on the adhesion of nails when driven into dry Christiana deal, at right angles to the grain of the wood.

	Number of lbs. Avoirdupois.	Inches long.	Inches forced into the wood.	Pounds re- quired to extract.
Fine sprigs,	4,560	0.44	0.40	22
Ditto,	3,200	0.53	0.44	37
Threepenny brads, ..	618	1.25	0.50	58
Castiron nails,	380	1.00	0.50	72
Sixpenny nails,	73	2.50	1.00	187
Ditto,	—	—	1.50	327
Ditto,	—	—	2.00	530
Fivepenny nails,	139	2.00	1.50	520

The percussive force required to drive the common sixpenny nails to the depth of $1\frac{1}{2}$ inch into dry Christiana deal with an iron weight of about 6½ lbs. was four blows falling freely the space of twelve inches, and the steady pressure required to produce the same effect was 400 lbs.

A sixpenny nail driven one inch across the grain into dry elm required 327 lbs. to extract it; driven endways, or longitudinally, it required 257 lbs. for its extraction: driven endways two inches into Christiana deal, it was drawn out by a force of 257 lbs.; but driven in one inch only in the same direction, it was extracted by 87 lbs. The relative adhesion, therefore, when driven transversely or longitudinally, is as 100 to 78, or about 4 to 3, in dry elm; and as 100 to 46, or as 2 to 1 in deal.

To extract a common sixpenny nail from a depth of one inch out of dry oak, required

Dry beech,

Green sycamore,

A common screw of $1\frac{1}{2}$ th of an inch diameter was found to have an adhesion about three times that of a sixpenny nail. The resistance to the entrance of a nail was found to be to that of extraction, in some experiments, as 6 to 5.

N A 1

is carbonate of soda found; and the waters of the sea are equally destitute of it. Nevertheless, on the sea-shore natron is formed, though in a small quantity, efflorescing at the surface; and here its origin must be attributed to the decomposition of the muriate of soda. This decomposition may be effected in various ways, and advantage is taken of this in the manufacture of artificial subcarbonate of soda, in which several methods, more or less perfect, have been successfully employed. It is probable, therefore, that it is from the natural decomposition of muriate of soda that natron is formed. The natron in Egypt, in the opinion of Mr. Berthollet, is produced by the reciprocal action of muriate of soda and carbonate of lime, assisted by efflorescence. The lakes of Egypt contain a great quantity of muriate of soda, and they occur in the midst of a calcareous formation, the rocks of which project here and there through the sand which covers them. Masses or beds of gypsum also occur, which probably accompany the deposits of rock salt which the waters traverse before arriving at the lakes. The same explanation will probably be found to be applicable to many other instances of the formation of natron, or mineral carbonate of soda.

NATURAL DAY, is the time the sun takes in passing from the meridian of any place, till it comes round to the same meridian again; but the natural days are not equal to one another; and *equation of time*, is the difference between the mean length of the natural day, (or 24 hours) and the length of any single day measured by the sun's motion, or between *mean time* and *apparent time*. For any natural day is the time in which the earth performs one revolution round its axis, and such a portion of the second as is equal to the sun's increment of right ascension for that day; but the sun's daily increments of right ascension are unequal, therefore the additional portion of the second revolution will sometimes be greater and sometimes less, and consequently, the times in which the natural days are completed will be unequal. If the sun were to move uniformly round the equator in the same time in which it appears to describe the ecliptic, its apparent daily motion would be a measure of mean time; for the natural days in that case being liable to no variation, either from the inclination of the sun's orbit, or the irregularity of its motion, must be equal.

NATURAL HISTORY, may be divided into two heads; the first teaches us the characteristic or distinctive marks of each individual object, whether animal, vegetable, or mineral: the second makes us acquainted with all its peculiarities, as to its habits, its qualities, and its uses.

NAUSEA, or Sickness, arises generally from something which irritates the stomach.

NAUTICAL INDICATOR, for finding the Latitude, Longitude, and Variation, invented by James Hunter, member of the Glasgow Philosophical Society.—The indicator consists of a stand supporting a circular plate of polished brass, about 14 inches in diameter, representing the horizon, and marked and numbered accordingly with the proper divisions. This horizon is surmounted by a semicircular plate, as a meridian, set at right angles to the plane of the horizontal plate, properly divided and furnished, with an index attached to a nonius indicating minutes. This meridian plate is cut out at the centre to allow room for a pivot, or hinge, for other parts of the indicator. On one side of this meridian are placed two quadrants, and on the other side one, similarly divided as the meridian, and furnished with a similar index and nonius. These quadrants are moveable on a pivot, or hinge, rising perpendicular from the centre of the horizontal plate; or, agreeing to this centre, they are singly moveable on the pivot, but capable of being attached at any relative distance, and retained in that situation by a screw, binding together tails attached for the purpose. To the east and west points of the horizontal plate is attached a horary circle, divided into hours, &c. This horary circle represents the daily path of the sun, and it may be furnished with a nonius, as other parts are. This circle is so attached to the horizontal plate, that it can be moved parallel to it, to suit the sun's declination; this is effected by the circle being attached to two tangent plates, which by grooves slide on the projections from the horizontal plate by means of screws passing through and working in these projections, and carrying the tangent plates, and with them the horary circle, to the degree of the sun's declination. This degree is indicated on a

scale of tangent divisions on the tangent plates, and as such tangents are of various lengths, an expanding vernier is used to adjust them. Its expansion is effected by friction wheels and springs working against a proper curve.

Elevation of Hunter's Nautical Indicator.

References to the Figures.—1, 2, 3, the quadrants of altitude, and also arches of azimuth circles; 4 is the apparent horizon, on which the azimuths and amplitudes are given; 5, the horary circle, on which the hours and minutes of time are given; 6, the scale of declination, with an expanding vernier; 7, 8, 9, sliding indexes, with their respective thumb screws; 10, a sliding stop; 11, continual screws for setting the indexes of declination; S, the support, on which the instrument turns; M, the meridian.—*Note.* The same references agree both to the plan and elevation.

Use of the Indicator.—Its use is to discover the latitude, longitude, and variation of the compass, without a meridian observation; or to find the whole path of the sun and the ship's place, by having ascertained a small portion of his path. Thus the indicator will frequently supersede the necessity of calculations—will prove their accuracy—or correct their inaccuracies, and enable an ordinary seaman to supply the place of captain or mate, in case of necessity. It will be of the most important utility in case of inconstant, stormy weather, when observations of the meridian altitude of the sun are unobtainable.

Manner of using the Indicator.—1st. By the side screws and scales, the horary circle is to be so adjusted to the declination of the day of the month, as marked in the tables of declination. 2d. An observation of the sun by Hadley's or other quadrant, is to be taken, and the moveable quadrant for that from the meridian, adjusted by its index to the observation. Also, an hour, or any practical time after, another observation is to be taken and noted on the other moveable quadrant in the same manner, noting the time elapsed between the observation by any well-going watch, and then connecting both to move together. Then the indices of the two quadrants are to be applied to the scale on the edge of the horary circle, at the distance noted by the intervening time, and at such part of the circle, that both indices will accurately touch its edge. In this contact each index will indicate the true time of the observation. The index on the meridian, brought into contact with the horary circle, will give at the same time the sun's true meridian altitude, and the latitude of the ship's place. The place of the quadrant on the horizontal plate, will give the true bearing of the sun at the time of observation. The true time of observation at the ship is to be compared by the chronometer with the time at the radical meridian, and the difference reduced into degrees and minutes, gives the longitude—the difference between the true bearing of the sun, found as above, and the bearing given by the compass, is equal to the variation at the place of observation, and the index on the meridian gives the latitude. Thus the decision, or ascertaining of the

three great points, is facilitated, and nearly reduced to inspection, viz. latitude, longitude, and variation. If the one observation is taken A. M. and the other P. M. the moveable quadrant on each side is used. If both observations are obtained P. M. the quadrant nearest the meridian is first used.

Plan of Hunter's Nautical Indicator.

In the year 1817 Mr. Hunter exhibited his invention in Glasgow; in November, 1823, there appeared in the London Magazine the following notice of an instrument for finding the latitude at once, without the help of Logarithms or Calculations, from two observations, taken at any time of the day:—The inventor of this instrument, Joseph Bordwine, Esq. professor of fortification at the East India Company's Military College at Addiscombe, took out a patent for his discovery, and the Court of Directors issued orders that this instrument be henceforth used throughout the whole of their naval department. Mr. Bordwine's nautical instrument is intended to put within the reach of every commander of a vessel, the solution of that important problem in navigation, viz. the determination of the latitude by two observations of the sun, or other celestial body, taken at any period of the day, a problem which has engaged the attention of scientific men for a long time past, with the view of rendering the forms of calculation more simple than by the old method. The instrument does away with calculation altogether, giving the results in itself. It is formed of four circular arcs, (the greatest about nine inches in diameter,) having a common centre, and traversing about each other. On two of these are scales for the declination of the object observed, and on the other two scales for the altitudes which are taken for the usual instruments, quadrant, &c. There is also a fourth semicircle, fixed in position, for the time elapsed between the observations. In working it, the declination for the day is set off, the time adjusted, and the verniers, marking the observed altitudes, brought together, when the instrument will immediately shew,

1. The latitude of the place of observation, to 15' of a degree. 2. The distance in time from noon of either observation, to 2' of time, which compared with a chronometer will give the difference of longitude. 3. The true azimuth, which, compared with a compass bearing, will give the variation of the magnetic pole. The operation may take about three or four minutes, there being no other calculation required than the usual correctness for dip, refraction, &c. In the altitudes; and the like for the declination, from the Nautical Almanack, to adapt it to the place of observation: these being reductions which must take place under any solution of the problem, whether by the calculated forms, or by instrument. Two or three hours' instruction will make any master of a vessel competent to use it.—This account of Bordwine's instrument amounts also to a demonstration, that it is the same as Hunter's, which, however, claims priority of date for its invention.

NAUTILUS, in Natural History, a genus of the vermes testacea class and order. The *N. pompilius* inhabits the Indian and African oceans, often very large, and finely variegated with brown fawnous streaks, spots, and marks under the outer

covering, which is white; within of a most beautiful pearly gloss. Of this species, the inhabitants of the East make drinking cups. The shell of *N. papyraceus* is no thicker than paper, and the fish is not fastened to it. When it is to sail, it expands two of its arms on high, and between these supports a membrane which it throws out on this occasion; this serves for its sail; and the other two arms it hangs out of its shell, to serve occasionally either as oars or as a steering, but this last office is generally served by the tail. If a storm arises, or any thing gives them disturbance, they draw in their legs, and take in as much water as makes them specifically heavier than that in which they float, and they sink to the bottom. When they rise again, they void this water by a number of holes, of which their legs are full.

NAVE, in Architecture, denotes the body of a church, or the place where the people are seated, reaching from the rail or baluster of the choir to the chief door.

NAVE of a Wheel, that short thick piece in the centre of a wheel, which receives the end of the axle-tree, and in which the ends of the spokes are fixed.

NAVIGATION, the art of sailing, or of conducting a vessel through the ocean, is usually divided into navigation common, and navigation proper; the former relating to what is otherwise called coasting, or traversing the coast or shore of a country, and in which the navigator seldom loses sight of land. And the other, to those voyages made from one country to another, through the trackless paths of the ocean. The origin of navigation, like that of all the arts and sciences of ancient date, is lost in obscurity, some attributing it to one nation, and some to another. The Phœnicians, particularly those of Tyre, are now, however, more generally considered as the first people who made any great advances in this important art. These were afterwards followed up by the Carthaginians, who discovered the Fortunate or Canary Islands, and even, according to some authors, America was visited by this enterprising people, but of this there is not sufficient proof. From Carthage and Tyre commerce and navigation were transferred to Alexandria, which when under the Romans was only inferior to Rome itself, the latter being supplied with its merchandise wholly from the magazines of the former. Constantinople became afterwards the centre of commerce, and navigation was for a long time pursued with great ardour by the merchants of that city; after this time it began to spread itself, though slowly, amongst the several European cities and nations. Genoa and Venice are particularly distinguished for the active part they took in promoting this important branch of human knowledge. The crusades, however, contributed in a great measure to its revival, and the Genoese, the Pisans, and Venetians, who furnished transports to those holy mariners, pushed their discoveries to a great extent. The inventor of the mariner's compass in the fourteenth century completed the wants of sailors. Columbus and Vasco di Gama immortalized themselves in the fifteenth century, and Cook in the eighteenth, by their noble discoveries.

A few plain truths will set the whole art of navigation in a clear light to the most inexperienced.

1. In whatever direction a ship sails, she must steer along some rhumb or point of the compass. Thus, supposing she were going to sail from New Guinea to Nippon, one of the Japan islands, in long. 150° east, her course would be due north along the meridian of 160° east long. If she were going to sail from New Holland to Madagascar, her course would be due west, in the latitude of about 20° south; and so on of her course in any other direction between the four cardinal points of the mariner's compass. Hence,

2. In *plane Sailing*, the angle formed by the meridian and rhumb that a ship sails upon, is called the ship's course. Thus, if a ship sails on the N. N. E. rhumb, then her course will be 22deg. 30min.; and so of others.

3. The distance between two places lying on the same parallel, reckoned in miles of the equator, or the distance of one place from the meridian of another, counted as above on the parallel passing over that place, is called meridional distance, which in plane sailing goes under the name of Departure.

4. Let A, fig. 2, denote a point to the earth's surface, A C its meridian, and A D the parallel of latitude passing through

it; and suppose a ship to sail from A on the N. N. E. rhumb, till she arrives at B, and through B, draw the meridian B D, (which by the principles of plane sailing must be parallel to C A,) and the parallel of latitude B C, then the length of A B is called her distance; A C or B D will be her difference of latitude or northings, C B will be her departure or easting, and the angle C A B will be the courses. 5. Since the distance, difference of latitude, and departure, form a right-angled triangle, in which the oblique angle opposite to the departure is the course, and the other its complement, therefore, having any two of these given, we can, by plane trigonometry, find the rest; and hence arise the following cases of plane sailing.

Case 1. Course and distance given, to find the difference of latitude and departure.

Example. Suppose a ship sails from the latitude 30 deg. 25 min. north, N. N. E. 32 miles, fig. 3, required the difference of latitude and departure, and the latitude come to, (by right-angled trigonometry,) we have the following analogy for finding the departure, viz.

As radius 10-00000

to the distance A C 32 1-50515
so is the sine of the course A 22 deg. 30 min. 9-58284

to the departure B C 12-25 1-08799
so the ship has made 12-25 miles of departure easterly, or has got so far eastward of her meridian. Then for the difference of latitude or northing the ship has made, we have (by rectangular trigonometry) the following analogy, viz.

As radius 10-000000

to the distance A C 32 1-50515
so is the sine of the course A 22 deg. 30 min. 9-58284

to the difference of lat. A B 29-57 1-47077
so the ship has differed her latitude, or made of northing 29-57 minutes.

And since her former latitude was north, and her difference of latitude also north, therefore,

To the latitude sailed from 30° 25' 0" N.
add the difference of latitude 00 29 57

and the sum is the latitude come to 30 54 57

By this case are calculated the tables of difference of latitude and departure to every degree, point, and quarter-point, of the compass.

Case 2. The course and difference of latitude being given, to find distance and departure.

Example. A ship in the latitude of 45 deg. 25 min. north, sails N E by N easterly, (fig. 4,) till she comes to the latitude of 46 deg. 55 min. north; required the distance and departure made good upon that course. Since both latitudes are northerly, and the course also northerly, therefore,

From the latitude come to 46° 55'
subtract the latitude sailed from 45 25

and there remains 1 30

the difference of latitude equal to 90 miles. And (by trigonometry) we have the following analogy for finding the departure B D, viz.

As radius, sine 90° 10-00000

is to the diff. of lat. A B 90 1-95424
so is the tangent of course A 33-22 9-91404

to the departure B D 73-84 1-86828
so the ship has got 73-84 miles eastward of her former meridian. Again, for the distance A D, we have (by trigonometry) the following proportion, viz.

As radius 10-000000

is to the secant of the course 39-22 10-11176
so is the diff. of lat. A B 90 m. 1-95424

to the distance A D 116-4 2-06800

Case 3. The difference of latitude and distance given, to find course and departure.

Example. A ship sails from the latitude of 56 deg. 50 min. north, on a rhumb between south and west, 120 miles, and she is then found by observation to be in the latitude of 55 deg. 40 min. north; required the course she sailed on, and her departure from the meridian. (Fig. 5.) Since the latitudes are both north, and the ship sails towards the equator, therefore, From the latitude sailed from 56° 50'
subtract the observed latitude 55 40

and the remainder 1 10
equal 70 miles, is the difference of latitude.—By rectangular trigonometry we have the following proportion for finding the angle of the course F, viz.

As the dist. sailed D F 126° 2-10037

is to radius 10-00000
so is the diff. of lat. F D 70 1-84510

to the co-sine of the course F 56° 15' 9-74473
which, because she sails between south and west, will be south 56 deg. 15 min. west, or SW by W. Then, for the departure, we have (by trigonometry) the following proportion, viz.

As radius sine 90° 10-00000

is to the dist. sailed D F 126° 2-10037
so is the sine of the course F 56 15' 9 91985

to the departure, D E 104-8 2-0222
consequently she has made 104-8 miles of departure westerly.

Case 4. The difference of latitude and departure given, to find the course and distance.

Example. A ship sails from the latitude of 44 deg. 50 min. north, between south and east, till she has made 64 miles of easting, and is then found by observation in the latitude of 42 deg. 56 min. north; required the course and distance made good. Since the latitudes are both north, and the ship sailing towards the equator, therefore,

From the latitude sailed from 44° 50' N
take the latitude come to 42 56

and there remains 1 54
equal to 114 miles, the difference of the latitude or southing.

In this case (by trigonometry) we have the following proportion to find the course K G L, (fig. 6,) viz.

As the dist. of lat. G K 114° 2-05880

is to the radius 10-00000
so is the departure K L 64 1-80618

to the tangent of the course G 29° 19' 9-74928
which, because the ship is sailing between south and east, will be south 29 deg. 19 min. east, or S S E½ east, nearly. Then for the distance we shall have (by rectangular trigonometry) the following analogy, viz.

As radius 10-0000

is to the diff. of lat. G K 114° 2-05880
so is the secant of the course 29° 19' 10-05884

to the distance G L 132-8 2-11648
consequently the ship has sailed on a S S E½ east course 130½ miles.

Case 5. The distance and departure given, to find course and difference of latitude.

Example. A ship sails from the latitude of 34 deg. 24 min. north, between north and west, 124 miles, and is found to have made of westing 86 miles; required the course steered, and the difference of latitude or northing made good. In this case (by trigonometry) we have the following proportion for finding the course A D B, fig. 7, viz.

As the distance A D	124°	2:0934
is to radius sine 90°		10:0000
so is the departure A B	86	1:93450
to the sine of the course D	43 54'	9:84108

so the ship's course is north 33 deg. 45 min. west, or NW by N $\frac{1}{2}$ west nearly. Then for the difference of latitude we have (by rectangular trigonometry) the following analogy, viz.

As radius sine 90°	10:00000
is to the distance A D	124° 2:09342
so is the cosine of the course	43° 54' 9:85766
to the diff. of lat. B D	89 35 1:95108

which is equal to 1 degree and 20 minutes nearly. Hence, to find the latitude the ship is in, since both latitudes are north, and the ship sailing from the equator, therefore,

To the latitude sailed from	34° 24'
add the difference of latitude	1 29

the sum is 35 53
the latitude of the ship is in north.

Case 6. The course and departure given, to find distance and difference of latitude.

Example. A ship at sea, in the latitude of 24 deg. 30 min. south, sails SE by S, till she has made of easting 96 miles; required the distance and difference of latitude made good on that course.

In this example (by Case 2-) we have the following proportion for finding the distance, fig. 8, viz.

As the sine of the course G	33° 45'	9:74474
is to the departure H M	96	1:98227
so is radius		10:00000
to the distance G M	172 8	2:29753

Then, for the difference of latitude we have (by rectangular trigonometry) the following analogy, viz.

As the tangent of course	33° 45'	5:82489
is to the departure H M	96	1:98227
so is radius		10:00000
to the diff. of lat. G H	143 7'	2:15738

equal to 2 deg. 24 min. nearly. Consequently, since the latitude the ship sailed from was south, and she sailing still towards the south,

To the latitude sailed from	24° 30'
add the difference of latitude	2 25

and the sum 26 55
is the latitude she is come to, south.

Observation. When a ship sails on several courses in 24 hours, the reducing of all these into one, and thereby finding the course and distance made good upon the whole, is commonly called the resolving of a traverse. At sea, they commonly begin each day's reckoning from the noon of that day, and from that time they set down all the different courses and distances sailed by the ship till noon next day, upon the log-board; then from these several courses and distances, they compute the difference of latitude and departure for each course, by Case 1, of Plane Sailing, and these, together with the courses and distances, are inserted in the Traverse Table, which consists of five columns; in the first are placed the courses and distances, in the two next, the differences of latitude, north or south, belonging to these courses; and in the two last, the departures, east or west, belonging to these courses. Then the persons who keep these reckonings, sum up all the northings and all the southings, and taking the difference of these, they know the difference of latitude made good by the ship in the last 24 hours, which will be north or south, according as the sum of the northings or southings is greatest. In the same manner, by taking the sum of all the eastings, and likewise of all the westings, and subtracting the lesser of these from the greater, the difference will be the

departure made good by the ship during the last 24 hours, which will be east or west, according as the sum of the eastings is greater or less than the sum of the westings; then from the difference of latitude and departure made good by the ship in the last 24 hours, found as above, they find the true course and distance made good upon the whole, (by Case 4, of Plane Sailing,) as also the course and distance to the intended port.

Of Parallel Sailing. Since the parallels of latitude are concentric circles to the axis of the earth, they always decrease the nearer they approach the pole; it is plain, therefore, that a degree of longitude on any of them must be less than its corresponding degree of longitude upon the equator. See the Table of DEGREES OF LONGITUDE.

Now, to know the length of a degree on any of them, let P B, fig. 9, represent half the earth's axis; P A a quadrant of a meridian, and consequently A a point of the equator; C a point on the meridian, and C D a perpendicular from that point upon the axis, which plainly will be the sine of C P, the distance of that point from the pole, or the co-sine of C A its distance from the equator; and C D will be to A B as the sine of C P, or co-sine of C A, is to the radius. Again, if the quadrant P A B is turned round upon the axis P B, it is plain the point A will describe the circumference of the equator whose radius is A B, and any other point C upon the meridian will describe the circumference of a parallel whose radius is C D.

Fig. 7.

Fig. 8.

Fig. 9.

Fig. 10.

Cor. 1. Hence (because the circumferences of circles are as their radii) the circumference of any parallel is to the circumference of the equator, as the co-sine of its latitude is to radius. 2. And since the wholes are as their similar parts, the proportion will be, as the length of a degree on any parallel, is to the length of the degree upon the equator, so is the co-sine of the latitude of that parallel to radius. 3. Hence, also, as radius is to the co-sine of any latitude, so are the minutes of difference of longitude between two meridians, or their distance in miles upon the equator, to the distance of these two meridians on the parallel in miles. 4. And, as the co-sine of any parallel, is to radius, so is the length of any arc on that parallel (intercepted between two meridians) in miles, to the length of a similar arc on the equator, or minutes of difference of longitude. 5. Also, as the co-sine of any one parallel, is to the co-sine of any other parallel, so is the length of any arc on the first in miles, to the length of the same arc on the other in miles.

Of Mercator's Sailing.—Though the meridians all meet at the pole, and the parallels of latitude from the equator to the pole continually decrease, and that in proportion to the co-sines of their latitudes; yet in sea-charts the meridians are drawn parallel to one another, and consequently the parallels of latitude made equal to the equator, and so a degree of longitude on any parallel is as large as a degree of longitude on the equator; also in these charts the degrees of latitude were still represented (as they are in themselves) equal to each other, and to those of the equator. By these means the degrees of longitude being increased beyond their just proportion, and the more so the nearer they approach the pole, the degrees of latitude at the same time remaining the same, it is evident places marked down upon those charts with respect to their latitude and longitude, and consequently their bearing from one another, must be very false. To remedy this inconvenience, so as still to keep the meridians parallel, we lengthen the degrees of latitude in the same proportion as those of longitude are, that the proportion in easting and westing may be the same with that of places from one another are the same upon the chart as upon the globe itself.

from one another, viz. north, south, east, and west: that of the meridian which extends itself from the place to a point of the horizon is called the north line; that which extends to the south point of the horizon is called the south line; that part of the prime vertical which extends to the right hand of the observer when his face is turned north, is called the east line; and lastly, that part of the prime vertical which tends towards the left hand, is called the west line; the four points in which these lines meet the horizon are called the cardinal points.

In order to determine the course of the wind, and to discover any alterations or shiftings, each quadrant of the horizon intercepted between the meridian and prime vertical, is divided into eight equal parts, and consequently the horizon into thirty-two; and the lines drawn from the place on which the observer stands, to the points of division of the horizon, are called rhumb-lines; the four principal of these are those described in the preceding paragraph, each of which takes its name from the cardinal point in the horizon to which it tends: the rest of the rhumb-lines have their names compounded of the principal lines on each side of them, as in the figure; and over whichever of these lines the wind is directed, that wind takes its name accordingly. See COMPASS.

Running Currents, and the method of making proper allowance for their effects upon a ship's way.—Currents are motions of the stream, by which all bodies (as ships, &c.) therein, are compelled to alter their course or velocity, and submit to the motion impressed upon them by the

The great and general currents are from east to west throughout the tropical regions, and from north to south in the temperate regions, coinciding with the regular tropical winds. Along the shores of continents and islands they are diverted from their natural course, and being sometimes confined into a narrow channel, acquire an almost preternatural velocity; as the great current from east to west along the American continent. See CURRENT. The northern seas are moved by the action of the polar current, extending along the whole coast of Britain from the Orkneys south-

. If the current sets just the course of the ship, i.e. the same rhumb with it; then the motion of the ship is increased, by as much as is the drift or velocity of the current.

. If the current sets directly against the ship's course, the motion of the ship is lessened by as much as is the drift of the current.

Method of keeping and correcting a journal at sea, by proper allowances for the lee way, variation, &c.—1. The angle that the rhumb-line, upon which the ship sails, makes with the rhumb she really sails upon, occasioned by the force of the wind or surge of the sea, is called the lee way, or is close-hauled, which is liable to fall off and glide sideways from the point of the compass. Let NESW represent the compass; and a ship at C capes at, or endeavours to sail upon, the rhumb line *NE*; but by the force of the wind, and the surge of the sea, she is obliged to fall off, and sail upon a rhumb line *NEbE*; then the angle *NEC* is the lee way; and if that angle be equal to one point, the ship is said to make one point lee way; and if equal to two points, she is said to make two points lee way. The quantity of this angle is very uncertain, and some ships, with the same quantity of lee way, will make more than others.

Method of finding the lee way.—Let the ship's wake be set by a compass upon the opposite rhumb is the true course made the ship; then the difference between this and the rhumb given by the compass in the binnacle, is the lee way.

If the ship is within sight of land, then the lee way may be exactly found by observing a point on the land which is to bear the same way; and the distance between the point of the compass it lies upon, and the point the ship capes at, is the lee way. Having the course steered, and the

lee way given, we may from thence find the true course thus: Let your face be turned directly to the windward; and if the ship has her larboard tacks on board, count the lee way from the course steered towards the right hand; but if the starboard tacks are on board, then count it from the course steered towards the left hand. Thus, suppose the wind at north, and the ship lies up within six points of the wind, with her larboard tacks on board, making one point lee way; here it is plain, that the course steered is ENE, and the true course E by N; also suppose the wind is at NNW, and the ship lies up within six points of the wind, with her starboard tack on board, making 1½ point lee way, it is evident that the true course, in this case, is WSW.

We have this general rule for finding the ship's true course, having the course steered and the variation given, viz. let your face be turned towards the point of the compass upon which the ship is steered; and if the variation is easterly, count the quantity of it from the course steered towards the right hand; but if westerly, towards the left hand; and the course thus found is the true course steered. Suppose the course steered is N by E, and the variation one point easterly, then the true course steered will be NNE; also suppose the course steered is NE by E, and the variation one point westerly, then in this case the true course will be NE, and so of others. Hence, by knowing the lee way, variation, and course steered, we may from thence find the ship's true course; but if there is a current under foot, then that must be tried, and proper allowances made for it. After making the proper allowances for finding the ship's true course, and making as just an estimate of the distance as we can; yet by reason of the many accidents that attend a ship in a day's sailing, the latitude by account frequently differs from the latitude by observation, and when that happens, there must be some error in the reckoning; to discover which, and make its correction the reckoning, you may observe the following rules:—1st. If the ship sails near the meridian, or within 2 or 2½ points thereof, then if the latitude by account disagrees with the latitude by observation, it is most likely that the error lies in the distance run; for it is plain, that in this case it will require a very sensible error in the course to make any considerable error in the difference of latitude, which cannot well happen if due care is taken at the helm, proper allowances are made for the lee way, variation, and currents. Consequently, if the course is pretty near the truth, and the error in the distance runs regularly through the whole, we may, from the latitude obtained by observation, correct the distance and departure by account, by the following analogies, viz.

As the difference of latitude by account is to the true difference of latitude,

So is the departure by account
to the true departure,
And so is the direct distance by account
to the true direct distance.

If the courses are for the most part near the parallel of east and west, and the direct course is within 5½ or 6 points of the meridian; then if the latitude by account differs from the observed latitude, it is most probable that the error lies in the course or distance, or perhaps both.

The form of the Log-book and Journal, together with an example of a day's work, are here subjoined.

To express the days of the week, mariners commonly use the characters by which the sun and planets are expressed, viz. ☉ denotes Sunday, ☾ Monday, ♀ Tuesday, ♄ Wednesday, ♃ Thursday, ♀ Friday, ♄ Saturday, called respectively *Dies Solis*, *Dies Lunæ*, *Dies Martii*, *Dies Mercurii*, *Dies Jovis*, *Dies Veneris*, *Dies Saturni*.

From the following table it will be seen, that the ship by account, has come to the latitude of 47 deg. 48 min. north, and has differed her longitude 2 deg. 6 min. westerly; so this day I have made my way good, south 31 deg. 31 min. west, distance 157.4 miles.

At noon the Lizard bore from me north 31 deg. 31 min. east, distance 157.4 miles; and having observed the latitude, I found it agreed with the latitude by account. See LONGITUDE.

Inland Navigation, expresses more properly what relates to canals, rivers, and lakes, than the ordinary but well known word *Canal*. Egypt, the cradle of science, was the birth-place of the earliest canals, one of which, according to Herodotus, (lib. ii.) passed from the river Nile to the Red sea, and so vast that four ships could pass abreast. Its navigation was performed in four days. Aristotle (Met. lib. i. cap. 14.) says, a king attempted to draw a canal from the Red sea to the Nile, but abandoned the work because the Red sea was higher than the land of Egypt. Diodorus Siculus (lib. ii.) makes it communicate with the Pelusiac branch of the Nile. Strabo affirms, that in his time (lib. i. and xvii.) the merchants of Alexandria formed an outlet from the Nile in the Arabic gulf, to go on to India. It was, he adds, of 100 cubits breadth, and of depth sufficient for the largest vessels. Pliny says, (lib. xxvi. cap. 29 and 33.) it began near Bubasto, and went to the Red sea. The geographer Ptolemy calls it Trajan's river. During the glory of the Mahomedan conquests, Amrour, who conquered Egypt about 635, opened this canal from the Nile to Quotzoum on the Red sea, to convey the contributions of corn into Arabia. Elkmala tells us that it was shut up again by the Caliph Alman-

zor in 773. China abounds in canals, yet India is devoid of such means of transporting the produce of its rich soil; Persia has no inland navigation worth mentioning; Greece and Italy are alike destitute of these moveable roads, which afford in Holland, France, and Britain, such facilities to commerce. The United States of America now begin to rival France in canals. The canals in England are both numerous and grand; but outdone, perhaps, by the Forth and Clyde canal, and certainly by the Caledonian canal, which opens a communication between the Atlantic on the western coast of Scotland, and the German ocean, at the Murray Frith. The latter passes through Loch Ness, and allows vessels, drawing 18 feet water, to be traisted along. See the plan and details of this canal on the plate. But the canal in agitation to be cut between the English Channel and the Severn, to open a communication across the country, without doubling the Land's End, will be the most advantageous work of the kind constructed in England.

Theory of Canal Cutting.—It is evident, that in cutting canals, no farther excavation is required than that which will hold the water at the given depth and breadth; and since, according to the modern practice, a bank on either side is likewise made with the stuff excavated, it is evident, that if we make that bank of sufficient strength and closeness to contain the water, the level of the surface of the canal may be thereby raised above the natural surface of the land, and great part of the excavation saved. One of the first objects, therefore, in canal cutting, is to know at what height above the surface of the land the canal may be carried on level ground when the excavated stuff or cutting will just make the banks. This is called level cutting. When the ground along which the canal is carried has a declivity, the quantity of stuff to be applied to one bank is necessarily greater than that wanted for the other. This disparity may increase until the one bank vanishes, and the canal is cut entirely along the side of the hill, and only the lower bank is required to be made.

This is the simplest case of canal cutting, and the work admits of being laid out in a much more expeditious way than has commonly been employed, as will be seen: this case is called side cutting, or oblique cutting; the slope of the cut which is made in the hill being made the same as the exterior of the canal bank. These two lines in the section are parallel to each other; and there is a certain point in the section, through which, if any line be drawn, representing the surface of the ground in any case, which line we shall call the line of cutting the portion of the section thereby exhibited as excavation, will always be equal to that exhibited as embankment. We shall call this point the centre of cutting.

PROBLEM I.—Given the outline section or profile of a canal in sidelong ground, with parallel slopes. To find the centre of cutting.

Case 1. For one bank only. See plate I. CANALS, fig. 1.

Given A B C D a section of the canal, C D E G F, a section of the bank. To find the centre of cutting.

Produce the lines B C and E D to G and A. Draw the perpendiculars C m, D n, and the diagonals A G, m n intersecting in p. Through p draw the parallel e p t, and bisect it in o; o is the centre of cutting, through which, if any line H o F be drawn cutting the slopes A B and E G produced, the section H B C will always be equal to w D E F.

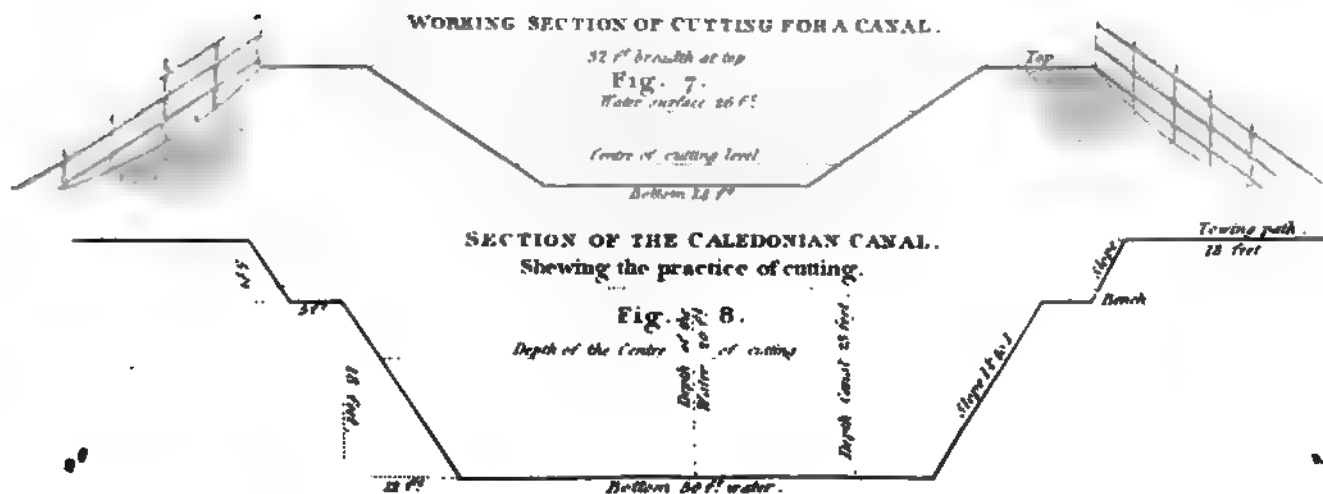

The centre of cutting is also the centre of cut and cover, for H o is always equal to o F. Hence, if a line be staked on along the ground at the level of the centre of cutting, it will exhibit the middle of the ground wanted for the use of the canal, whatever may be the inclination of the surface, at least if that inclination be regular as far as the breadth required and the distance o H or o F, on each side of the centre, may easily be found by a line drawn across the section with the given inclination of the ground.

The distance of the centre of cutting, from the centre of the canal at surface water, is equal to $w q + D E$. Hence, if the line of the middle of the cut and cover be laid out, or the centre of cutting, we may lay out a set of stakes at a certain horizontal distance therefrom; and the top of these stakes being made even with the level of surface water, they will exhibit the line of the middle of the canal when finished.

At half the general breadth A B, from the centre of cutting

INLAND NAVIGATION.

THE THEORY & PRACTICE OF CUTTING CANALS.

level, is a point in the exterior slope of the bank, of stakes may be set out at that distance and level, direct the wheeling of stuff for the formation of the road at these stakes a level and plumb line may be with the slope of the bank, by which the point F, exterior slope of the bank meets the surface of the be found, and may be marked out, and the edge of will be at an equal distance on the other side of the cutting.

same distance, viz. half the general breadth A E, and on each side of the centre of cutting, at its level is the the inner slope of the excavation.

horizontal distance ov , of the inner slope of the bank centre o , will be found by saying $Em : mC :: xo :$ of stakes may therefore be placed at this distance to direct the wheeling as above, and by a level and commencement of the bank and excavation may in the same way.

Quantity of excavation above the level of the centre of the triangle osH , and the base os will always be equal to the height Hy of the upper edge above the level. Quantity of excavation below the level of the centre of deriving from $sBCv$ only by the small triangle osv , the base os being constant, the area is proportioned perpendicular from w to the level of the centre of the

fig. 2. When there is a towing path on the upper side, B C D E G, as before, the profile of the path, canal, take $Dd = aA$, draw ab and cd parallel to the thereby converting the section $aA B C D E$ into $abcdE$, the towing path is supposed to be added to the bank; draw the lines aG , cd , and st ; the middle o will be the centre of cutting.

II.—Fig. 3. To reduce the section A B C D E F and bench or path EF, to the equivalent section, with one bank only, but wider and shallower, the it down and filled into the bottom.

BC and HF to Z, also CD to G; make DN = the parallel NL (or, if the slopes are all equal, perpendicular to GC,) on FL, describe the semi-circle F, cutting the perpendicular GM; make ZK (and to ZM; draw the parallel KI, and it is done. Height of IK over CG is nearly found by the slopes.

III.—Fig. 4. Given the profile of a canal with the slopes being all equal. To find the lines of the

the section A B C D into A H K E. For this find o , of cutting. Produce each slope to meet in V; draw perpendiculars VN, ON; with centre N and radius NV p ; make $Va = PQ$, and through a parallel to EA the line of level cutting.

IV.—Fig. 5. Given as in last problem. To find the oblique cutting.

the line of level cutting. Produce the slopes to meet in the perpendicular VI; from L draw LN with the slope of the ground, cutting VI in N, making Np and I, also VR = pI. Through R draw KRH for the oblique cutting required.

slopes are parallel, then $NR = NI$, and I is the centre of the centre cutting over level cutting, in this case the shallow cutting, is the difference between ozy and

V.—Fig. 6. Given the profile of a canal, as in and the line of ground level too low for level cutting. to widen the canal so as to have cutting for the

visions, that the trapezoid OM must be provided for parallelogram DQ, wherefore draw the perpendiculars, and make $Dp = RS$. Draw the parallels ON and I is the additional width, or CG is the mean bottom. calculation, as $NT : TO$, so $pD = Rs : DC$.

formed from LM by adding the slope base for the T at each end, and is usually $LM + 3MT$, or $3RS$. the problem to the above may be given for narrowing in deep cutting; but this is of less use; and it is that when the ground OK is at or below the bottom

CD, the problem is impossible, and the case becomes one of embankment.

Example. Fig. 7. Given a canal of 14 feet bottom, 26 feet water surface, the banks rising two feet over water, and 10 feet broad at top, slopes being $1\frac{1}{2}$ to 1, required the centre of cutting:

26	6 total depth.
6 = 2×3	1½

10	10 top bank.
42	10
	6

42) 60 (= 1½ feet, the height of the centre of cutting over the bottom of the canal.

$$\frac{42}{2} = 21$$

21 feet, is its distance from the inner slope of the upper, and from the outer slope of the lower side. From 6 deduct $1\frac{1}{2}$, and there will remain 4½, which multiplied by $1\frac{1}{2}$ will give 6¾, to which add 6 the half breadth of top bank, and the sum 11½ is the distance from the middle of the canal.

$$1\frac{1}{2} \times 3 = 4\frac{1}{2}$$

14 bottom.

18½ breadth of canal at level of centre.

21 half total breadth ditto.

2½ distance of centre from outer slope of the canal; and it is evident, that the centre of cutting is in the bank in this case.

Example. Fig. 8. The Caledonian Canal has 50 feet bottom, and 20 feet water; the slopes are $1\frac{1}{2}$ to 1, to within two feet of surface water, where there is a bench or retreat of five feet; above this the banks rise five feet with a slope of two to one, and are 18 feet wide at top. On the upper side, in side-cutting, there is a bench or towing path of 10 feet. The area of the part on each side over the bench or retreat, if the inner slope was carried to the top, would be,

$$(5 + 7\frac{1}{2}) \times \frac{5}{2} = 31\frac{1}{2}, \text{ and the breadth at top is } 7\frac{1}{2} \text{ feet.}$$

$$\frac{31\frac{1}{2}}{23} \times 2 = \frac{62\frac{1}{2}}{23} = 2\frac{1}{2}.$$

So that the space contained over these benches is equivalent to widening the canal $2\frac{1}{2}$. The depth $23 \times 1\frac{1}{2} = 34\frac{1}{2}$, is the base of the inner slope if produced to the level of the top of the banks; whence $50 + 2 \times 34\frac{1}{2} = 119$, would in that case be the width of the canal. Also, $18 + 7\frac{1}{2} = 25\frac{1}{2}$ would be the breadth at top of the bank, and $10 + 7\frac{1}{2} = 17\frac{1}{2}$ would be the breadth of the upper bank; their sum, 43 feet, must be diminished by $2\frac{1}{2}$, and the width of canal increased by the same quantity, to allow for the recesses at top. Then say, as total width $119 + 43 = 162$ canal and banks to $43 - 2\frac{1}{2} + 34\frac{1}{2} = 74\frac{1}{2}$ top bank and one slope. So depth of canal 23. To depth below centre of cutting 10½, and consequently, the depth of said centre from the top, is $23 - 10\frac{1}{2} = 12\frac{1}{2}$.

Of the Form of Locks.—The most natural form of the lock is that which approaches, as nearly as possible, to the figure of the boats which are to use it. The width must be only a little more than that of the boat, and it must be the same throughout, as the boat has to pass along the whole lock; and the length may only exceed that of the boat by a space sufficient to admit of working the gates. A long rectangle is therefore the natural figure. It consumes the smallest quantity of water in passing the boat; is filled and emptied in the shortest time; and, on the whole, is constructed at less expense than any other form. See fig. 5, Caledonian Canal.

Having thus determined the preference to be given to locks of a rectangular form to those of a circular form, as in the canal of Languedoc, or the circular lock at Agde, figs. 1 and 3, our next object is to consider their length and

breadth. This must depend on the size of the vessels for which the locks are intended. When the vessels are to be navigated also on rivers or the sea, the breadth of the locks must be more considerable than where canal boats are intended to pass; for in rivers the shallow water frequently met with, obliges us to give the vessel an excess of breadth, so that her draft may be diminished as much as possible; whereas, in canals, we are masters of the depth of water, and find it more economical to restrict the breadth as much as possible, as we thereby diminish the evaporation, the expense of cutting, and the purchase of property. Dr. Anderson, and other writers on the subject of small canals, have not attended sufficiently to this matter, when they recommended widening the surface only of small canals in order to give a greater facility of trackage.

In our English canals, the usual size of boats supposed fit for the navigation of rivers and canals alternately, is one of 14 feet beam. Where the canals are intended also to be used by coasters, greater widths are adopted. Thus the Forth and Clyde Canal admits vessels of 19 feet beam; and the Caledonian canal, which is a canal of transit for sea-going ships, admits vessels of 39 feet wide; but in the great majority of canal navigations in England, a much smaller width has been adopted. Seven feet beam has been the usual size in the central canals, and still narrower boats have been proposed; but they become liable to many inconveniences, and can only be employed in the transport of very heavy substances, such as ores or minerals. The narrow boat has the advantage of being navigated with more ease, and of causing less expense in lock-gates, bridges, &c.

Length and Breadth of Locks.—The length and breadth of lock chambers ought to be necessarily regulated by the form of the boats that are to pass upon the canals. It is common to make this kind of boats longer and narrower than those of rivers, which, on account of the small depth of water found in some places, are obliged to be made as flat as possible. In canals, on the contrary, we are able to give a considerable depth to the water, but we do not give them great breadth, so that there may be less evaporation, less earth to be removed, and less ground to be occupied. There is commonly no more breadth given to canals than what is necessary for enabling two boats to navigate with ease beside each other, and even in the difficult parts, such as those which are cut in rock, there is often no more breadth given than what is necessary to pass a single boat, only some places are made wider, at which one boat may lie by, while another one passes in an opposite direction. Besides, a principal object in making use of narrow boats on navigable canals, is to diminish the breadth of the lock-gates, which wear longer, and are more easily worked, than when they are broad. Narrow boats are also more easily drawn than those which are wider and shorter. But what ought principally to regulate the width and breadth of locks are the dimensions of those in the canals already executed, and through which the boats of the new canal may have to pass.

Coehorn, in his fortification, has given a very ingenious construction for a retaining wall. His designs were intended for the soil of Holland, where stone is not to be found, and it behoved him to be as sparing of masonry as possible. His wall is only three feet thick, battering considerably in front, and leaning nearly as much behind, supported by long and thin counterforts, which are connected together by two rows of arches, one over the other; and also by two walls arched horizontally against the earth. The intervening spaces are filled with gravel and splinters for the purposes of defence, which is also the reason of his counterforts being made so long, and connected by double walls. Coehorn does not give this as his own invention, though he describes it very carefully, but as having been adopted by him from some older German authors.

Gauthey, a civil engineer in the French service, who constructed the canal of Charolois, or of the Centre, about thirty years ago, has published a very sensible paper on the subject of walls, in the *Memoirs of the Academy of Dijon*. After criticising the theories of Couplet and others, given in the *Transactions of the Academy of Paris*, and the profiles of Belidor and Vauban, he proceeds to shew, by experiments made with sand and shot against a smooth plane, that the pressure acts at the centre of gravity, or one-third of the height of the wall,

and is the same whatever be the slope; that in a plumb wall, if the height of the wall be three times the acting power of the earth, and base $\frac{1}{3}$ ths of the height, there is an equilibrium against oversetting. The acting power in practice is one fourth of the weight of the triangle of the earth, with a slope of 45° , or one-half of the square of the wall.

He then shews, that retreats on the back of the wall may be made, so as to take off all acting power, and that a wall of 2 feet thick, and 30 high, battering $\frac{1}{4}$, with counterforts of 3 by 4, and 18 asunder, joined by two arches of 2 ft. thick, is abundantly strong. Such a wall be employed with success for one of the quays of the Saone; and it is evident, that the saving of masonry compared with the common construction is immense.

But in the walls of locks more must be attended to than the pressure of the earth alone. A film of water inserted between the back of the wall and the earth, will act hydrostatically against each of them, will counteract the aid which might be derived from friction, and if the lock be emptied in that state, may overset the wall inwards. But the hydrostatical pressure of the water within the lock can hardly do any harm, seeing the motion of the wall must be prevented by the resistance of the earth behind; hence, the utility of counterforts behind the wall, is mainly that of cutting off the communication between one portion of such a film of water and another, so that the action being confined to a smaller space is the less dangerous, as the wall also derives a kind of abutment from the counterforts. The upper part of the lock-wall, so far as the water rises and falls thereon, is (unless water be very abundant) usually made perpendicular, its thickness therefore must be so calculated as to resist the pressure of water of equal depth, and, taking the specific gravity of stone as 2½ times that of water, this thickness will be the depth multiplied into 0.365, or a little more than $\frac{1}{3}$, and one half the depth will be sufficiently ample in any case.

The lower portion of the lock may be suited to the shape of the vessels which navigate through it, and therefore it will permit the wall to be made with a considerable batter, or slope to the front, by which means the point of conversion being farther removed from the centre of gravity of the wall, the stability will be considerably increased without an increase of materials; but it must be observed, that the point of conversion itself must be sufficiently secured. To prevent sliding, it ought to be inserted some way into the ground of the foundation. If built upon a timber platform, it ought to be provided with an abutment; and if upon piles, they ought to be driven in the direction of the thrust, which will be nearly that of the face of the wall. Now, as the opposite wall of the lock requires the same precautions, and its action is directly in face of the other, by joining the bottom of the walls by an inverted arch, we not only destroy the horizontal thrust, but also extend the foundation, which, in the case of soft ground, becomes of great importance. The inverted arch has been much employed in this situation by our late British engineers. On the Continent, we believe it is still the practice to rely on a platform of timber, or even a simple flat pavement, especially where the ground is firm. See the figures of the locks for the Canal of Burgundy, figs. 1 and 3 of the Plate.

In the timber countries, as Russia, America, and even Holland, where stone is scarce, there are locks of which not only the floor but even the sides are constructed of wood. In such cases, the thrust of the opposite sides are sometimes made to balance each other by cross pieces over the lock, placed between the upright posts which support the planking of the sides. Instances of this may be seen on the river Lea, but the practice is not certainly to be recommended.

This will tend to float the lock upwards like a ship, and unless the weight of the side-walls be sufficient to counteract this, the bottom or floor will give way, or be blown up, as is the technical phrase. The floatation of a timber floor will aid this operation, while the weight of an inverted arch will to a certain extent resist it. This forms one of the greatest objections to timber locks, and in them it is perhaps advisable that the dams of sheet piles should not be brought below the upper gates; but as all locks must at times be emptied for the purpose of repairs, &c. we have still the head of water of the lower pond, or ordinary depth of navigable water, to be resisted. The floor

therefore must be carried a considerable way into the land, and thereby loaded by the adjoining earth; or, if built within a river, it must be kept down with stones, &c. laid over the cross beams projecting on each side. This is the construction of a lock on the Witigra canal. Or the floor and sides may be bolted to piles driven as firm as possible into the bottom, thereby as it were nailing the lock to the ground. The floatation of the lock and weight of the side-walls will counterbalance each other when the section of the masonry in the walls and bottom is two-thirds the area of the open space of the lock. Plate II. fig. 10. The average thickness of the walls, therefore, where there is no invert, would require to be one-third of the width of the lock. Where there is an invert, the thickness will be much less, but may be readily found from the above. Brick walls would of course require a greater thickness than those of stone; and here we may perceive the importance of those means by which the weight of the adjacent earth is made to rest upon the back of the wall, for we thereby obtain an additional counterpoise against the floatation without expense. Puddling behind the walls is therefore resorted to with great propriety. See fig. 11, Plate II.

It is needless in this place to be more minute in the calculation for the thickness of the walls; the principle may be easily understood and applied when wanted. Besides, with respect to locks, it is rather an extreme case, as they are rarely exposed to greater differences of pressure than the ordinary rise of the navigation. For tide-locks, and graving-docks, however, it is of high importance to guard against the hydrostatic pressure on the bottom; and serious accidents have taken place where it has not been sufficiently attended to. We proceed therefore with the practical construction of the lock itself. The site and dimensions of the lock being determined, the first object is the excavation of the lock-pit, or place for the foundation. In small canals and navigations carried above the level of the neighbouring valleys, this is seldom attended with any difficulty, the excavation being in most cases level free for drainage; but in great locks connected with rivers, lakes, or the sea, it is often necessary to go to a considerable expense; and in many cases, all the resources of hydraulic engineering are required to keep the excavation clear of water, or, when that is impracticable, to make a foundation independent of it.

The varieties of soil and situation render it impossible, in such a work as this, to give general rules for proceeding in all cases. We have already given some general principles under the article Bridge, which will, we believe, be most useful for the young engineer, even in constructing canals. Several good examples of lock making, that occurred in the construction of the Caledonian Canal, shall now be produced.

Caledonian Canal.—Locks.—The Caledonian Canal is not only constructed on an unusually large scale, but, in consequence of various localities in the situation of its works, it affords much practical information to the civil engineer. Some of the most important instances are in regard to the sea-lock at each extremity of the navigation; also that which is placed at the upper or south-western end of Loch Ness at Fort Augustus.

With regard to the lock at the north-east extremity.—The shore of Loch Beaul, where the canal was to be connected with the tideway at Clachnacarry, near Inverness, being very flat, it was necessary to carry the canal, by artificial embankments, above 400 yards from high water mark into the sea, in order to obtain 20 feet of water upon and without the lock sills, at high water of neap tides. But this shore consisting of soft mud, into which an iron rod was easily pressed to the depth of 55 feet, it became doubtful whether a sufficiently substantial cofferdam could be constructed of timber, and also if any platform could be made equal to support the weight of masonry unavoidable in a lock of 180 feet in length, 40 feet in clear width, having 20 feet of water, besides a rise of 8 feet. Upon duly considering all the circumstances, a new mode occurred to the conductors of that work, and that was, by uniting the two earthen banks which were projected from the shore, at the place where the site of the lock was fixed, so as to form a solid mound over all the space which the lock would occupy; and this was done for the purpose of squeezing out the water and consolidating the mud, by laying on a greater weight than the masonry of the lock: this was accordingly carried into effect.

73.

By the latter end of the year 1809, the mound was carried out to the necessary length, breadth, and height, and during its construction had sunk about 11 feet. A great quantity of stone was then laid upon the space the lock was to occupy, and levels taken to ascertain the precise height of the banks; in this state matters were suffered to remain for about six months, until August 1810, when, having found that no farther sinking had taken place, the excavation for the lock-pit was commenced in the before mentioned artificial mound; a chain-pump, worked by six horses, kept the pit dry when sunk to 15 feet in depth. At that time a steam-engine, of nine-horse power, was erected, by which the water was commanded, and the excavation of the lock-pit was completed in June 1811. Before getting down, to about 30 feet below the level of high water ordinary springs, it was necessary to penetrate into the compressed mud about 8 feet, and the small portions of water which filtrated through the surrounding mounds of earth (in which puddle walls had been carried up) was conducted in small gutters along the top of the compressed mud to the pump-well. As soon as the lock-pit had been excavated, rubble masonry, with lime mortar, was laid about two feet in thickness in the middle of the lock-chamber, and increasing to about 5 feet at each side; upon this the side-walls were founded, and brought up to the level of the top of the compressed mud, and then the inverted arch of squared masonry was put in, and the side-walls, counterforts, recesses, and wings, carried regularly up; the masonry of the bottom part was carried on by short lengths of about 6 yards at one time, in order to prevent the compressed mud again softening and being squeezed together in the open space. The above mentioned mud was found to be readily penetrated by piles, but when these were suffered to remain a few hours, no power could move them. The masonry of the lock was very successfully completed in August, 1812; the gates were afterwards put up, and the lock has been worked for several years. The whole is now in a very perfect state.

Corpach Lock.—The circumstances under which the lock at the south-western end of this navigation was constructed, differ greatly from what we have just described. It was found necessary to connect the canal with the tide-way in Loch Eil, at Corpach, on the north-west side of the rock, situated about 100 yards from high water; this rock was covered at three-fourths flood; and the lock was to be advanced so far into the sea, as to admit of the sill being laid upon the rock, where there should be 30 feet of water upon it at high water neap tides. For this purpose, water-tight mounds, faced with stone, were carried from the shore to beyond the extremity of the lock site. Between the extremity of these mounds, a wooden cofferdam was constructed. The clearing away the gravel, sand, and mud, the fixing the main piles firmly in the rock, and placing the wooden frames correctly in their proper places, were operations of considerable difficulty; but the success which attended a work of this magnitude and exposure, renders this mode deserving the attention of persons engaged in similar, or even inferior undertakings. Under the article BRIDGE foundations, we have minutely detailed every step of the process, and it would be an unnecessary repetition to introduce the description here; we therefore presume it will be sufficiently satisfactory to refer to that article. Only, it may be farther observed, that when the water had been excluded, and the rock excavated, no inverted arch was necessary.

Fort Augustus Lock.—The ground upon which the five connected locks at Fort Augustus were to be placed, consisting of coarse open gravel, and the lowermost of these requiring to be constructed so as to admit 20 feet of water upon the lower gate-sills at the lowest state of the water in Loch Ness; and the large river Oich, running upon the same sort of gravel, and close along the site of the lock, rendered it an arduous task to keep very large lock-pits clear of water; for the rise of these locks being only 8 feet, the foundations of the second and third locks were also considerably incommoded by water. This site for these locks being by much the most eligible for the navigation, it was absolutely necessary to endeavour to surmount these natural obstacles. The first step was, in 1814, to turn the whole of the river Oich to the northernmost side of a small island, and occupy part of the south channel by the locks. A trial-pit was next to be sunk; and, by means of a

8 T

small steam-engine, of about six horse-power, it was carried to the depth of 18 feet; but here the water overpowered it. A pump-well was then begun, and an engine of 36 horse-power, which had previously been provided, was erected. It commenced working in August, 1816, and the excavation of the lock-pit was carried on with all possible energy. It was continued as long as the flood-waters of the Oich would permit—was again commenced as soon as the state of the river would admit, in 1817, and during that summer and autumn, the whole masonry of the lock, bottom, and wings, and the forebay, were got in; but, in order to command the water effectually, the engineer had, during that time, caused to be erected a third engine, of about nine horse-power, which happened also to be in readiness; and when the excavation was upwards of 25 feet below the surface of Loch Ness, and the whole of the gravel still coarse and open, the power of all the three engines was required. These lock-pits being sunk directly into a mass of gravel, no cofferdam could be of any service. Under the inverted arch and side walls of the lock, chamber, &c. rubble masonry of a sufficient thickness was constructed; but it was here laid upon, and mixed with, abundance of moss, and this was done in order to prevent any shifting sand from percolating. At the latter end of the working season of 1818, the whole masonry of the lowermost lock had been built, also the inverted arch, and 14 feet in height of the side walls of the second lock; and likewise the inverted arch, and 6 feet of the walls of the third lock; so that, except for the purpose of putting up the gates, there could be no farther occasion for employing the steam-engines at Fort Augustus, and every risk was at an end. In these three locks, there has, therefore, been afforded, cases of soft mud, hard rock, and very loose gravel, as foundations for very large locks. For their form and dimensions, see Plate II. figs. 5, 10, and 11.

The sheet piles, or plank piles heretofore alluded to, being of frequent use in hydraulic architecture, may be as well described in this place. They are sawn out of a thickness proportional to the strain they are intended to bear. The points are gradually sharpened so as to have a bevel or chamfer to one side only, so that in driving, each may be forced close against the preceding one; still farther to secure the seam or joint against the transpiration of water, it is not uncommon to groove the piles on one edge, and make a ridge or feather on the other to fit these grooves, so that the piles are, in driving, preserved in the same plane. Lastly, to save timber, the pile is frequently grooved on each side, and a slip or feather, which may be of harder wood, driven in between, so as to enter both grooves. The plank piles are preserved in position, by being spiked to sills, or horizontal beams of timber, extending in the line of the proposed sheet plank piling, and fastened to stout upright piles of baulk, placed at certain distances in the same line, called gauge piles.

In the construction of a lock, one of the earliest objects of attention is the platform on which the gates are to traverse. It is usually formed of timber. A stout floor of plank is spiked or tree-nailed down upon sills, or transverse beams, which are laid across the lock, and their extremities built into the walls. The scantling of the sills and plank are proportioned to the fatigue they have to undergo. In great locks, there are usually two rows of whole baulk in thickness, laid close together over the whole floor, carefully bedded in a mass of water-tight rubble masonry; and, when the foundation is doubtful, longitudinal ground sills are laid below, then resting, if need be, on piles driven to a proper depth. A row of grooved sheet piles is driven across the lock at the upper and lower end of this platform, and the floor is carefully caulked to prevent any transpiration of water.

On this platform the sill of the lower gates is placed; its construction is that of tie beam and two rafters, having the angle or curve of the lock gates; and as it has the thrust of the water to withstand, care must be taken to give it sufficient abutment. The platform of the upper gates is constructed in all respects similar to the lower. The sheet piling at the lower side is unnecessary; but care must be taken that the breast-wall or step of the lock be made water-tight, and carefully puddled upon the upper side. To prevent also its receiving any derange-

ment from the blows of boats, &c. it is necessary to lay a wooden curb along the coping of this breast-wall.

In Ireland, timber has been sparingly used in the construction of locks; good stone and mortar are, in general, easily procured there. The platform for the gates is made of hewn stone. The sill is of hewn stone, set on edge, and usually two feet deep, supported on the lower side by a horizontal arch, which, at the upper gates, forms the coping of the breast of the lock; and, to resist blows from vessels, the key-stone of this arch is supported by two struts of horizontal flagging passing to the sides of the lock, or by a counter arch in the hewn pavement of the platform.

In constructing the side walls, a recess is made on each side, to permit the gates to fall back out of the way of vessels; and it is not uncommon to make those for the upper gates act as waste-weirs or overfalls, to discharge the superfluous water of the canal into the paddle holes. These paddle holes are conduits of stone or brick, usually of a circular form, and about 18 inches diameter, by which the water of the upper level is conveyed into the lock chamber. From the lock it is usually conveyed into the lower level through sluices or paddles formed in the gates, below the level of the lower water; but, in the upper gates, this is seldom practicable, for the breast of the lock being commonly higher than the lower level, a cascade would thereby be formed in the lock, which would be troublesome or dangerous to the vessels.

The conduits or paddle holes from each side are sometimes united at the back of the breast-wall, and discharge themselves through that into the lock. At other times they enter the lock separately in each side. In either case, the low level is preserved back to the place of entry, and the water is then permitted to fall down on a flat surface in the conduit, so as to break its progressive force as much as possible. The paddle itself is usually a square of cross planked wood, sliding up and down in a rabbeted frame of timber, fixed in the stone mouth of the conduit or paddle hole. The lateral pressure of the water makes it adhere closely to the frame, so that it is necessary not only to make it run with the grain of the wood, but also to have a considerable power to move it. This is done by a crank and pinion, working into a toothed rack, which is fixed on a bar or handle, rising from the paddle up to the top of the bank or gate. Sometimes screws are used instead of rack and pinion, and various other ingenious contrivances have been proposed, so as to make the paddle turn on an axis, either in its own plane, or at right angles thereto, like scouring gates, &c. One of the simplest modes we have seen of getting rid of the hydrostatic pressure and friction was proposed by Mr. John Duncombe, viz. to make the entrance or mouth of the paddle hole a horizontal circular opening, and stop it by an open cylinder ground to fit it, and rising of the same diameter to the surface, where it could be lifted by a lever or other means, like the waste pipe employed in some cisterns. The waste water of the canal would of course escape over the upper lip of the cylinder, and pass along the paddle holes as usual. Such a cylinder may be made of wood or iron.

The hollow quoins are upright circular grooves wrought in the side walls at the extremities of the sills; they serve as a hinge-place for the gate, the upright post of which that turns in them is named the heel of the gate; the opposite posts which abut against each other are called the head-posts. The heel-posts are retained in their places by a pivot or gudgeon at bottom, turning in a cup set in the stone, and sometimes the reverse, the cup being set in the heel-post. The upper part of the post is embraced by an iron strap or collar, which is carried back some way into the side wall, and firmly secured. The hollow quoins are commonly cut out of large scantlings of stone, or brick is moulded for the purpose, and cast-iron has also been employed on the Caledonian canal. The exterior portion of the lock above the upper and below the lower gates, are named the forebay and tailbay of the lock. The side walls are then made to splay away outwards to the usual breadth of the canal, so as to facilitate the entrance of vessels, and still farther to guide them; there are not unfrequently fender-beams, supported on piles, continued to some distance above and below the lock, and running into the bank on either side.

Strapping-posts are also used to check the way of the boats

on entering the lock; and, in the passage-boats on the canals in Ireland, a broad shield of iron is placed on each side of the stem, and dropped under the quarter when the boat approaches a lock. It is readily hauled up again when the boat gets under way. It is the invention of Mr. Sisson Darling, late secretary to the Grand canal.

Lock-gates are framed usually of timber, though iron is also used in some of the small canals in England, and has lately been introduced in framing the large gates for the Caledonian canal. The head and heel-posts are connected by cross-beams or rails turned therein; the upper and lower bars are firmly attached by straps and bolts, and the whole planked over, usually in an oblique direction, by way of giving an additional stay to the framing. The head-posts must be brought truly to the angle of abutment. If of iron, they have a ribband of timber bolted thereon, to soften the blows they receive. The heels must be wrought to a circular form to fit the hollow quoins, into which the pressure of the water will force them home. The upper bar of the gate, in small canals, is usually continued a considerable way beyond the heel-post, and left as heavy as possible, or is loaded so as to form a counterpoise to the weight of the gate, and a lever for opening it. In great locks, capstans are employed to work chains, leading to the middle of the head-post on either side. Various other contrivances have been adopted for opening and shutting the gates of large locks. In Holland, a boom or spar is commonly attached to the head-post, and brought over a windlass on the lock-wall, a little above the gate; a rope is made fast to the end of the spar, and taking two or three turns on the windlass, the spar end is carried to the other end of the spar, which thus, by means of the windlass, is made either to open or shut the gate. At Antwerp, the French have employed a rack-bar of wrought iron nearly in the same way. These heavy gates have usually a roller or truck-wheel placed under the foot of the head-post, and running on a quadrantal railway of iron, to facilitate their motion. With the same view, also, attempts have been made to give floatation to heavy gates. In Sweden, some gates were made for the dock of Carlscrona, which were to sink into a deep recess, and rise when wanted by the admission of, and again pumping out of, a quantity of water, on the principle of the machine called the camel. At the dock of Monnikendam is the best, and we believe the oldest, boat-gate now in use. It has three parallel keels, which fit into grooves in the side walls, and, by admitting water, and extracting it again, it is made to sit down in its place, or float up so as to be removed when necessary; but though such vessels are peculiarly useful as stop-gates, or for docks, they are not well adapted to a constant or much frequented navigation.

Reservoirs.—The mode of supplying a canal plentifully with water, being essential to its prosperity, it generally employs the attention of the engineer, previous to determining the most advisable line. When it is necessary to establish a navigable communication between separate valleys or basins of country, and where a double lockage is unavoidable, the summit which divides them is generally too high to permit a regular supply of water being drawn directly from the streams on either side; or these streams are not unfrequently appropriated to the service of mills and manufactories, as in the cases of the Languedoc canal in France, the Grand Junction and many others in England, and the Forth and Clyde canal in Scotland. Under these circumstances, it becomes necessary to collect the flood-waters of the adjacent higher grounds into proper reservoirs, to be drawn off as occasion may require. The choosing a proper situation for a great reservoir, requires all the skill of the engineer. Much must always depend upon local circumstances, but some of the principal objects to be had in view, are, 1st. That the reservoir should be sufficiently low to collect the flood-waters from an ample surface of country. 2d. It should be so high as to enable all the water it contains to be drawn into the summit of the canal. 3d. It is desirable that the basin to be laid under water, should contract towards its lower extremity, so as to require a comparatively short embankment or head; and this head should be placed upon a substantial foundation. 4th. It is very important that the bottom and sides of the reservoir should be naturally impervious to water, otherwise much trouble and expense will be required

to render them so, by artificial means. 5th. The dimensions of the embankment will be regulated by its height, and the nature of the materials with which it is to be constructed. It is, however, usual to assume the height of the top bank to be from three to four yards above top water when the reservoir is full; the breadth of the top to be five yards; the outside to slope at the rate of three horizontal to one perpendicular, and the inside slope at the rate of two horizontal for one perpendicular.—But these and similar erections must depend almost entirely upon the nature of the country, and the localities of situation, for which no specific rules can be given. Indeed, it is worthy of notice, and the consideration may lead to renewed exertions, that in the various branches of inland navigation in this country, the most valuable inventions and improvements have not originated so much in the depth of science, as in the application of practical skill, and ingenious experiment founded on a few general principles.

Summary of our Observations on Canal Locks.—The most natural form of a lock is that which approaches nearest to the figure of the boats which are to use it. The width must only be a little more than that of the boat, and it must be the same throughout, as the boat has to pass along the whole lock; and the length may only exceed that of the boat by a space sufficient to admit the opening and shutting of the gates. A long rectangle is the natural figure of a boat, and therefore of a lock; besides, it will consume less water than a circular dam in passing the boat; and may be filled and emptied in three minutes, as is the case with the locks of the Clyde and Forth canal in Scotland; moreover, the expense of construction, agreeably to this form, is less than any other shape. The locks of Languedoc canal, in France, are circular or oval, see figs. 1 and 3. Those of the canal of Brussels and others in Holland, are rectangular, but of such extensive chambers as to admit several vessels at once, which is attended with waste of water, and great delay in the passage of the boats. Tide locks, as those of the great Sas at Slykens, near Ostend, may admit several vessels of from 300 to 800 tons. The length and breadth of every rectangular lock should be proportioned to the size of the vessels or boats designed to pass through this lock, as in the Caledonian canal, fig. 5, where the length is 175 feet, and the breadth 40 feet. Canals of the first order, as the Forth and Caledonian, admit vessels of 19 and 30 feet beam, fig. 6; canals of the second class, vessels of 14 feet beam; and central canals, or those of the third class, 7 feet beam. In England there are but two kinds of canals, called large and small section canals, according as their breadth and the size of their locks permit the passage of large or small boats. All the canals, of large and small size, have not a determined relative size of locks, but they rarely exceed, in their difference of dimensions, the following proportions:

		Sections.
Canals { large }	} sections, length of the locks	{ 75 . 6
		{ 75 . 6
	Width of the lock-gates	{ 15 . 1
		{ 8 . 0

Of the Profile of Lock-walls.—The late Mr. Jessop made these walls of equal thickness from the base upwards, leaning them backwards, so as by retiring the centre of gravity, to enable the wall to resist better the lateral pressure. The natural slope of the triangle of earth is chamfered off at the angle of repose, or 35 degrees. If A B C D, in the figure, be the

erection of the wall, and BC the moveable part of the earth supported by the wall; then taking G the centre of gravity of the earth, and F that of the wall, and drawing the perpendiculars GH, GI, GK, and FL; GH represents the direction of the gravity of the earth, GI the direction of the

support given by the firm inclined plane CE, and GK of the horizontal thrust against the wall ABCD. The back of the wall is supposed to be smooth, and of course only to be acted upon perpendicularly; and the wall itself to be a solid mass, which can only be turned over the front angle of its base, or toe of the wall D. It resists this by its own weight, which may be supposed to be concentrated in the centre of gravity, and to act in the vertical line FLW. If W represent the weight of the wall, and P the horizontal thrust of the earth, MD and DL will be the two arms of a lever by which these forces are kept in equilibrio.

Now we know that MD or KC are two-thirds of BC; that the weight of earth is proportional to the area BCE, that is, to one-half of $BC \times BE$; and that this weight in GH is to the thrust in GK as EB is to BC. The thrust is, therefore, equal to $\frac{1}{2} BC^2$; and multiplying by its distance MD from the fulcrum D, that is, by $\frac{1}{3} BC$, we have its oversetting force equal to $\frac{1}{6} BC^3$. Consequently, the oversetting force of earth supported by walls of equal thickness is as the cube of the height. Now for the counter resistance of the wall, it is evident that its weight will be as the area ABCD, which in a rectangular wall is $BC \times CD$; and in that case also we will have the distance LD from the fulcrum = $\frac{1}{2} DC$, or that the resistance is $\frac{1}{2} BC \times CD^2$, making this force equal to the former, or $\frac{1}{6} BC^3$, we find $CD = BC \sqrt{\frac{1}{3}} = .8165 \times BC$.

The breadth of an upright retaining wall, must therefore be proportional to the height, and, to be of equal specific gravity with the stuff, must be upwards of four-fifths of the height. This, however, is different from what is found sufficient in practice. A brick wall, to support earth, is made four-sevenths of its height; of a stone wall $\frac{2}{3}$, or about half the height, when the earth is supposed to act not parallel to the horizon, but in lines parallel to the slope EC. The wall cannot fall on the side next the earth, therefore, by making it lean backwards, not only is the triangle of earth or acting power diminished, but also the wall itself, by having its centre of gravity removed further from the point of conversion at the toe, is the better enabled to resist the thrust. It batters in the form of a mere pavement over the slope of earth; all that is necessary, being to secure the foot from sinking or sliding forwards into the canal.

Cochorn, adopting the opinions of some old German engineers, and designing walls for the soil of Holland, gives them three feet of thickness in front, and leaving nearly as much behind, supported by long and thin counterforts, that are connected together by two rows of arches one over the other, and also by two walls arched horizontally against the earth.

Gauthey, a French engineer, who constructed the canal of Charalois, shews, by experiments made with sand and shot against a smooth plane, that the pressure acts at the centre of gravity, or one-third of the height of the wall, and is the same whatever be the slope; that in a plumb wall, if the weight of the wall be three times the acting power of the earth, and base two-ninths of the height, there is an equilibrium against over-setting. The acting power in practice, is one-fourth of the weight of the triangle of the earth, with a slope of 45° , or one-half of the square of the wall. He then shews that retreats may be made in the back of the wall so as to take off all acting power, and that a wall 2 feet thick and 30 feet high, battering $\frac{1}{4}$, with counterforts of 3 by 4, and 18 asunder, joined by two arches of 2 feet thick, is abundantly strong. Such a wall he employed with admirable success, for one of the quays of the Saone; and it is evident, that the saving of masonry, compared with the common construction, is immense. Brick on bed, with a sufficient batter, and corbels made by laying one brick endways in the wall, so that half of it projects behind, will create a sufficient friction to allow 20 courses to be piled against loose sand without derangement. In locks, allowing for the film of water that may insinuate itself between the masonry and the earth, taking the specific gravity of stone as $2\frac{1}{2}$ times that of water, the proper thickness will be the depth multiplied by 0.365 or little more than $\frac{1}{3}$, and one-half the depth will be sufficiently ample in any case. The upper part of the wall is usually perpendicular, the lower suited to the shape of the vessels, or rounded off.

The walls of the quays of one of the basins of the Fosseley canal, are covered with plates of cast-iron, joined by tenons and mortises fixed to the masonry with screw bolts; and in this canal we descend 246 feet by 36 locks in a space of eight miles. Mr. Telford, in the fine construction of the aqueduct of Pont-y-Cysylltan,* 126 feet above the level of the river, and 1010 feet in length, erected nineteen metal arches on eighteen piles of brick, to two abutments of stone; above these arches of the aqueduct of Chirk, he built side walls with brick in the usual manner, but with stone coating. Between these walls he laid down large plates of cast-iron, for the bottom of the canal, carefully clamped, then fastened with iron pins, screwed and caulked in the joints: these plates serve at the same time as continued holdfasts, in order to prevent the side walls from being thrown downwards by the pressure of the fluid. To give the structure a greater resistance against the pressure of the water, the sides of the canal are composed of strong plates of wrought-iron, not cut straight, but so formed as if they were a continuation of the lines presented by the solid parts of the ribs of the bridge; and the plates which join the parts of one arch with those of another, are wider at the bottom than at the top, which produces the same effect as that of buttresses supporting a wall. The lower portion of the lock may be suited, we said, to the shape of the vessels which navigate it, and therefore it will allow the wall to be made with a considerable batter, or slope, to the front, by which means the point of conversion being farther removed from the centre of gravity of the wall, the stability will be considerably increased without an increase of materials; the point of conversion, to be sufficiently secured to prevent sliding, ought to be inserted some way into the ground of the foundation.

There is yet another principle by which the profile of the lock-wall must be regulated; the transpiration of the waters from the upper pond to the lower, beneath, or by the side of the lock, must be prevented. This is effected by rows of

Fig. 1.

Fig. 2.

the line of the proposed sheet plank piling, and fastened to stout upright piles of balk, placed at certain distances in the same line, and called gauge piles. The film of water that is filtered under the floor of the lock being connected with the upper pond, acts upwards by a pressure equivalent to the head of water, or difference between the waters above and within the lock, and unless the weight of the side walls be sufficient to counteract this, the bottom of the floor will give way, and be blown up. The floatation of a timber floor, and the weight of an inverted arch, will, in some measure, counteract this, when the section of the masonry in the walls and bottom is two-thirds the area of the open space of the lock. We may assume the specific gravity

* The archduke John of Austria, when viewing the magnificent aqueduct of Pont-y-Cysylltan, expressed astonishment that nothing had been published respecting a structure, "which," said the prince, "in France would have produced three folio volumes!" What a fine compliment on the merit and modesty of Mr. Telford?

[illegible]

ding, (see fig. 3.) $2\frac{1}{2}$ times water: it will therefore for an opening of $1\frac{1}{2}$ times the whole is immersed: is no invert, the average of the walls is one-third of the lock; when there is, they may be much less. Locks connected with rivers, long roads and feeders of connected with lakes or the resources of hydraulic are put in requisition.

Fig. 3.

recting the side walls of locks, a recess is made, to gates to fall back out of the way of vessels, as is the canal of Languedoc, and the Caledonian canal, 5, Plate of Locks; and it is not uncommon to make the upper gates act as waste weirs, fig. 7, Plate of overfalls, to discharge the superfluous water of the paddle-holes, or conduits of stone or brick 18 meter, by which the water of the upper level is conducted the lock chamber. From the lock it is usually conducted the lower level through sluices formed in the gates, with the level of the low water. The paddle is moved and pinion working into a toothed rack, see fig. 2, or portion of the lock, above the upper and below gates, is named the forebay and tailbay of the lock, Caledonian canal. The lock gates are usually framed figs. 2 and 4, though, I believe, iron is greatly used in canals in England. I know it was used in framing the of the Caledonian canal, (see the Plate Locks, GATES, and 8,) and in the New Graving Dock at Dundee. purpose of securing water in the locks, solid parallel chambers, raising and depressing boats in frames, by chains passing over large wheels, and of working air vessels, have been projected and tried but seldom in practice. Inclined planes connecting canal levels have existed in China from time immemorial they have been long usefully employed in England of rail road.

weirs are either constructed across rivers, to force from them into the conducting feeders, or into the canal itself, or they permit the surplus water the canal. It is also requisite to have wastes adjacent, to convey water from upper to lower levels, with through the locks. To canals belong also aqueducts, oblique arches, or skewed bridges, stop-gates, &c. See Locks and Docks.

implies in general any fleet or assemblage of ships which belong to a kingdom or state.

arts and professions which attract notice, none is so fishing and marvellous than navigation in its present paring the small craft of antiquity to a majestic first-ringing 1000 men, with their provisions, drink, furniture, and other necessities for many months, besides of heavy ordnance, and bearing all this vast appa-ly to the most distant shores. How great is the dis-100 lbs. of provisions are required daily in such a ship. or fitted out for three months, we shall find her laden 100 lbs. of provisions. A cannon, if called a forty-two weighs about 6,100lb, if made of brass; and about if made of iron; there are twenty-eight or thirty of board a ship of 100 guns; their weight, exclusive of ages, amounts to 183,000lbs. On the second deck, twenty-four pounders; each weighing about 5,100lbs. ore altogether, 153,000lbs.; and the weight of twenty-five pounders on the lower deck, amounts to about fourteen six-pounders on the upper deck, to 28,000lb. round tops, there are three-pounders and swivels size. The complete charge of a forty-two-pounder out 64lb., and upwards of 100 charges are required on. All this amounts nearly to the same weight as themselves. Every ship must be provided against, with two sets of sails, cables, cordage, and tack-stores, likewise, consisting of planks, pitch, and small arms, bayonets, swords, and pistols, make no

inconsiderable load, to which we must finally add the weight of the crew; so that one of those large ships carries at least 2000 tons burden, and at the same time is steered and governed with as much ease as the smallest skiff on the Thames.

The British naval force, during the late war, (on the 1st of January 1813,) was as follows:—at sea 79 ships of the line; nine from 50 to 44 guns; 122 frigates; 77 sloops and yachts for bombs, &c.; 161 brigs; 54 cutters; 52 schooners, &c. In port and fitting, 39 of the line; 11 from 50 to 44 guns; 29 frigates, hospital ships, prison ships, &c. 28 of the line; two from 50 to 44; two frigates; one yacht. Ordinary and repairing for service, 77 of the line; 10 from 50 to 44 guns; 70 frigates; 37 sloops; 3 bombs, 11 brigs; 1 cutter; 2 schooners. Building, 20 of the line; four from 50 to 44 guns; 15 frigates; 5 sloops, &c. 3 brigs.

A fleet of ships of war is generally divided into three divisions; and commanded by admirals, vice-admirals, or rear-admirals, of the white, blue, and red flags.

A squadron of ships is a division or part of a fleet commanded by a commodore, or by a rear or vice-admiral. The number that forms a squadron is not fixed, for a small number in a body and under one commander may make a squadron. If the ships are numerous they are sometimes divided into three squadrons, and each squadron may be again divided into three divisions.

A frigate is a light-built fast sailing ship, having commonly two decks, whence that called a light frigate is a frigate with only one deck. These vessels mount from 20 to 44 guns, and make excellent cruisers.

Hulks are old ships cut down to the gun-deck, and fitted with a large wheel for careening. Their gun-decks are from 113 to 150 feet long, and from thirty to forty feet broad; they will carry from 400 to 500 tons. Hulks are also employed at Woolwich, Portsmouth, Sheerness, &c. to receive convicts under sentence of transportation; the vessels are moored at such a distance from shore, as precludes the possibility of the men's escape; and the convicts are taken daily on shore to work, under a strong guard, at pile-driving, harbour cleansing, and other employments in the several public departments.

A hoy is a small vessel or bark, whose yards are not across nor the sails square, like those of ships, but the sails like a mizzen, so that she can sail nearer the wind than a vessel with cross sails can do.

Sloops are appendages to men of war, about 60 tons burden, and carrying 30 men. They are light vessels, with only a small main-mast, fore-mast, and lug-sails to haul up and let down, on occasion, and are commonly fast sailers.

Smacks are small vessels with one mast; they sometimes are employed as tenders on a man of war: they are also used for fishing upon the coasts.

Store ships are generally ships of from 300 to 600 tons; they carry ordnance and military stores to the out-ports, or to an army when abroad.

A yacht, a vessel for the conveyance of passengers, is also sometimes adorned for regal use. It is furnished with masts and sails, has one deck, carrying from four to twelve guns with from twenty to forty men; burden from thirty to 100 tons. They are used for running, and making pleasure excursions.

A galley is a low-built Mediterranean vessel, having oars and sails. Gallies have usually twenty-five or thirty benches of oars on each side, and four or five galley slaves on each bench. The galley usually carries a large gun, two bastard pieces, and two small pieces. It is from twenty to twenty-two fathoms long, three broad, and one deep, and has two masts, viz. a main-mast, and a fore-mast, which may be struck or lowered at pleasure.

Naval Distinctions in Rank.—The Lord High Admiral of England is an officer of great trust; the king is nominally Lord High Admiral, while the duties of the office are executed by commission, called the Board of Admiralty, consisting of five commissioners denominated Lords of the Admiralty, one of whom, as resident, is called First Lord.

The Board of Admiralty takes cognizance of every thing transacted at sea, the management of all maritime affairs, the direction of the navy, and both civil and criminal offences committed on the high seas. Under this court is also a court

merchant, or court of equity, where all differences between merchants are decided according to the rules of the civil law. This court is held three or four times a year at the Old Bailey, and one of the judges generally acts as the Lord Admiral's deputy.

An Admiral is a great officer, who has the government of a navy, and the bearing of all maritime causes. In our navy, besides the admiral in chief, there are the Vice-admiral, who commands the second squadron; and the Rear-admiral, who commands the third division. The admiral carries his flag at the main; the vice-admiral, at the fore-top mast head; and the rear-admiral at the mizzen. The admiral ranks with generals in the army.

A Captain commands a ship of the line of battle, or a frigate carrying twenty or more guns. He is not only answerable for any bad conduct of the military government and equipment of the ship which he commands, but also for any neglect of duty.

A Lieutenant, an officer next in rank and power to a captain, in whose absence he commands, musters the men at quarters; visits the ship during the night watches; exercises the men in the use of small arms. First-rates have six lieutenants; a sixth-rate has only one.

Midshipmen, generally youths appointed by the captain of the ship, second the orders of the superior officers, and assist in all duties on board or ashore. In a first-rate there are twenty-four of these, in inferior rates from eight to four.

A Pilot conducts the ship into harbour through intricate channels. This is properly a coasting pilot; one for the high seas can use the quadrant, take observations, and steer a ship from port to port.

The Purser receives the victuals, takes care they be good, and regularly served out to the ship's company. According to the purser's books the men receive their pay. The Steward acts under the purser.

The Victualler furnishes the ship with provision and stores. The Clerk sees that nothing be wasted, and keeps a journal of the loading of a merchant ship, &c. the bargains, purchases, and sales the ship makes from its departure; the consumption of provisions; and every thing relating to the expense of the voyage. In small vessels the master or mate is also clerk. A mate is the second in subordination, as a master's mate.

The Surgeon and Chaplain resemble the same officers in the army.

Marines have nothing to do in working the ship, but defend it in war, and attack the enemy when fighting. There is generally a company aboard each ship, about forty in number, under a captain and two lieutenants. The present establishment of marines amount to more than 30,000. Their principal stations are at Chatham, Woolwich, and Portsmouth. In a sea-fight their small arms are of very great advantage in scouring the decks of the enemy, and when they have been long enough at sea, they must be infinitely preferable to seamen, if the enemy attempts to board, by raising a battalion with their fixed bayonets.

Officers of the navy are, the treasurer, who receives monies out of the exchequer to pay charges of the navy. The controller, who attends and controls all payments of wages, knows all the rates of stores, examines and audits all accounts. The surveyor knows the state of all stores, sees all wants supplied, estimates repairs, &c. and at the end of each voyage, audits and states all accounts. The clerk of the acts records all orders, contracts, bills, warrants, &c.

Navy bills, or victualling bills, are orders for the payment of money, issued by the commissioners of the navy on the treasury of the navy, in payment for stores, &c. furnished by contract for the use of his majesty's dock yards, and the navy. These bills, since 1796, are negotiated like bills of exchange, payable at ninety days after date, and bearing interest at 3½d. per cent. per diem. The privileges conferred on sailors are much the same as on soldiers, with regard to relief, when maimed, wounded, or superannuated. Greenwich Hospital receives such seamen as are disabled from further service, and provides for the widows and children of such as are slain.

The royal Navy of Great Britain is conducted under the direction of Lords of the Admiralty, by the following principal

officers, who are commissioners, and compose the board for managing the business thereof. 1. Comptroller of the navy, who attends and controls the payment of all wages, as to know the rates of stores, &c. 2. Supervisor of the navy, who is to know the state of all stores, to supply what is wanting, to estimate repairs, charge boatswains, &c. with the stores they receive, &c. There have been generally two joint surveyors. 3. Clerk of the acts, whose business is to record all orders, contracts, bills, warrants, &c. 4. Comptroller of the treasurer's accounts. 5. Comptroller of the victualling accounts. 6. Comptroller of the store-keeper's accounts. 7. One extra-commissioner. The annual appointment of each commissioner is 500*l*. In time of war, or great naval exertion, there are other extra-commissioners, and commissioners are then appointed to reside at some of the principal yards abroad. The treasurer of the navy has an appointment of 2000*l* per annum. His business is to receive money out of the exchequer, and to pay all the charges of the navy by warrant from the principal officers. Each of these commissioners and officers has a number of subordinate clerks with various salaries.

NAVY, is also used to denote the collective body of officers employed in his majesty's sea service.

Navy Board, the commissioners of the navy collectively considered.

Navy Office, the office where the accounts of the navy are kept.

NAZARENES, a term originally applied to Christians in general, but afterwards to the sect who blended the institutions of the Mosaic law with those of the gospel.

NAZARITES, among the Jews, persons dedicated to the observation of Nazariteship, either for only a short time, or all their lives. All that we find peculiar in the latter, is, that they were to abstain from wine and all intoxicating liquors, and never to shave or cut off the hair of their heads. The first sort of Nazarites were moreover to avoid all defilement; and if they chanced to contract any pollution before the term was expired, they were obliged to begin afresh.

NE ADMITTAS, in Law, a writ directed to the bishop, at the suit of one that is patron of a church, where on a *quare impedit*, &c. depending, he is doubtful that the bishop will collate his clerk, or admit the other's clerk, during the suit between them.

NEAP TIDES, are those which happen when the moon is nearly at the second and fourth quarters: the neap-tides are low tides, in respect to their opposites, the spring tides.

NEAPED, the situation of a ship which is left aground on the height of a spring tide, so that she cannot be floated off till the return of the next spring.

NEBULA, a luminous part of the heavens, called the Milky Way, which consists of myriads of fixed stars too small to be seen by the naked eye, and visible only by the best glasses. Some of these nebulae consist of clusters of telescopic stars; others appear as luminous spots of different forms. Each nebula is thought to be composed of a number of suns, and each sun is probably destined to give light to a system of worlds. There are also nebulous stars, that is, stars surrounded with a faint luminous atmosphere.

NECESSITY, whatever is done by a necessary cause, or a power that is irresistible, in which sense it stands opposed to freedom. The law charges no man with default where the act is compulsory, and not voluntary, and where there are not a consent and election; and therefore if either there is an impossibility for a man to do otherwise, or so great a perturbation of the judgment and reason as in presumption of law man's nature cannot overcome, such necessity carries a privilege in itself.

NECESSITY, *Philosophical*, maintains that the volitions and actions of intellectual agents are produced by causes equally deciding and resistless as those which are admitted to actuate the material system of the universe. Wherever the sun shines, or the rain descends, it is impossible to conceive, that in situations precisely similar to those which immediately precede these events, the ray should be withheld, or the cloud should remain suspended in the atmosphere. The diffused splendour, and the falling moisture, are universally allowed to be in such situations invariably and inevitably the results. The doctrine

of necessity extends to the mind what is thus obvious and uncontradicted with respect to matter, and insists on the absolute and uncontrollable influence of motives upon the human will and conduct. It asserts, that the determinations and actions of every individual flow, with unfailing precision and resistless operation, from the circumstances, motives, or states of mind by which they are preceded; and that, in the whole series of his existence, no specific feeling, thought, or act, could have been different from what it really was, these previous circumstances continuing the same. In the consideration of this subject, it is important not to confound necessity with compulsion, as the latter implies that the choice of the mind is effected with reluctance, and in consequence of the exercise of force upon inclination; whereas, whether the conclusion be formed with the full concurrence of the affections, or after a conflicting estimate, which leaves reason completely triumphant over inclination; the mind is equally impelled by some controlling energy, and equally necessitated to the determination it adopts. It is of consequence also to the illustration of the subject, fully to comprehend the meaning of the term motive, which, it is to be remembered, comprehends both the bias of the mind and the end in view, and includes every thing that moves or influences the mind, and excites it to a choice or determination.

NECROMANCY, a pretended divination by raising the dead and extorting answers from them.

Bolt Rope NEEDLE, a large needle with a triangular point, used to sew the bolt-rope upon the sails.

Sail NEEDLES, are needles used for sewing the seams of sails.

NE EXEAT REGNO, is a writ to restrain a person from going out of the kingdom.

NEGATIVE QUANTITIES, are those quantities which are preceded or effected with the negative sign.

NEGATIVE Sign, in Algebra, is that character, or symbol, which denotes subtraction, being a short line preceding the quantity to be subtracted, and is read *minus*; thus $a - b$ denotes that the quantity b is to be taken from the quantity a , and is read a minus b , like signs produce *plus*, and unlike signs *minus*, hence $-a \times -b = +ab$. The introduction of this character has given rise to various controversies, with regard to the legality or illegality of certain conclusions depending upon it; some maintaining, that as a negative quantity is in itself totally imaginary, it ought not to be introduced into a science, the excellency of which depends upon the rigour and certainty of its conclusions; while others running into the opposite extreme, have endeavoured to illustrate what will not admit of illustration; and thus, like other scabots, have been the greatest enemies of the cause they were so anxious to defend.

It is vain to attempt to define what can have no possible existence; a quantity less than nothing is totally incomprehensible; and to illustrate it, by reference to a debtor and creditor account, to say the least of it, says Barrow, is highly derogatory to this most extensive and comprehensive science.

NEGRO, a name given to a variety of the human species, who are entirely black, and are found in the torrid zone, especially in that part of Africa which lies between the tropics.

NEPA, *Water-scorpion*, a genus of insects of the order hemiptera, of which there are fourteen species, inhabiting stagnant waters, and preying on the smaller water insects, &c.

NEPENTHES, a genus of the diœcia syngenesia class and order, an herbaceous plant of Ceylon. The leaves are alternate, partly embracing the stem at their base, and terminated by tendrils, each of which supports a deep, membranous urn, of an oblong shape, and closed by a little valve like the lid of a box. In the morning the lid is closed, but it opens during the heat of the day, and a portion of the water evaporates; this is replenished in the night, and each morning the vessel is full, and the lid shut.

NEPETA CALAMINTHA. *Field Calamint*. *The Leaves*. This is a low plant growing wild about hedges and highways, and in dry sandy soils. The leaves have a quick warm taste, and smell strongly of pennyroyal: as medicines, they differ little otherwise from spearmint, than in being somewhat hotter and of a less pleasant odour; which last circumstance has procured calamint the preference in hysteric cases.

NEPETA CATARIA. *Nep* or *Catmint*. *The Leaves*.—This is a moderately aromatic plant, of a strong smell, not ill resembling a mixture of mint and pennyroyal; it is also recommended in hysteric cases.

NEPHRITE, in Mineralogy, a species of the talc genus; it is also called *jade* or *jade-stone*, and was formerly celebrated for its medicinal virtues. It is of a dark leek-green colour, verging to blue, and is found in Egypt, China, America, the islands in the Pacific ocean, and in the Siberian mountains, sometimes adhering to rocks, and sometimes in detached round pieces. It is highly prized by the Hindoos and Chinese, by whom it is made into talismans and idols, and by the Turks, who form it into sword and dagger handles.

NEPHRITIC, something that relates to the kidneys.

NEPHRITIC WOOD, a wood of very dense and compact texture, and of a fine grain, brought from New Spain, in small blocks, in its natural state, and covered with its bark. It is to be chosen of a pale colour, sound and firm, and such as has not lost its acrid taste. This wood is a very good diuretic, and it is said to be of great use with the Indians in all diseases of the kidneys and bladder. It is also commended in fevers and obstructions of the viscera. Among the Indians it is used only with an infusion in cold water.

NEPTUNIAN THEORY, in Geology, endeavours to account for the various geological phenomena, on the supposition that the matter of which the exterior part of the earth is composed was once in a state of watery solution. Its chief supporter is Werner. It is opposed to the Plutonic or Volcanic theory, which supposes the phenomena to have resulted from the matter of the earth having been in a state of fusion by fire; of this theory Dr. Hutton is the principal champion. That the surface of our globe was once in a fluid state, is established by very ample evidence. In the greater number of the strata of the earth, in the most elevated, as well as at the greatest depths, substances are found in a crystallized state; and even many of these strata have marks of crystallization in their entire structure. Crystallization is the arrangement of particles in a regular determinate form; and it necessarily implies a previous state of fluidity, which would allow these particles to arrange themselves in positions necessary to produce these forms. Many of the more solid strata contain in their substance remains or impressions of animals and vegetables: and it is obvious that, to admit of the introduction of such substances, they must at one time have been, if not in a perfectly fluid, at least in a soft or yielding state. In addition to this, the general disposition of the materials of the globe, so far as has been explored, must have arisen from fluidity, as this only could have arranged them in beds or strata, parallel to each other, and preserving that parallelism to a great extent. These appearances are not partial, but extend to the whole surface of the earth, and prove beyond a doubt its former fluidity. There are only two ways by which that fluidity can be supposed to have taken place: either the solid matter must have been fused by the action of heat, or it must have been dissolved in some fluid. These are the primary principles upon which the geological theories have been formed, under different modifications.

NEREIS, in Natural History, a genus of the vermes mollusca class and order. There are about thirty species, in separate divisions, found in most seas, and are highly phosphorous, giving a lucid splendour to the waves in the evening.

NERVES, cylindrical whitish parts, usually fibrous in their structure; or composed of clusters of filaments, arising from the brain, or rather from its medulla oblongata within the skull, and from the spinal marrow, and running from thence to every part of the body.

NET, a device for catching fish and fowl. The making of nets is very easy. All the necessary tools are wooden needles of different sizes, some round, and others flat: a pair of round-pointed and flat scissors, and a wheel to wind off the thread. The strength of the packthread, and the size of the meshes, must be according to the fishes or birds to be taken. The natural colour of the thread in many cases to be altered. The most usual colour is the russet, obtained by plunging the net into a tanner's pit, and letting it lie there till it be sufficiently tinged. A green colour is given by chopping some green

wheat and boiling it in water, and then soaking the net in the tincture. A yellow colour is given in the same manner with the decoction of oelandine, which gives a pale straw colour.

NETTING, a sort of fence, formed of an assemblage of ropes fastened across each other, so as to leave uniform intervals between. These are usually stretched along the upper part of a ship's quarter, to contain some of the seamen's hammocks, and secured in this position by rails and stanchions. Nettings are also used for containing the fore and main top-mast stay-sails when stowed.

Boarding NETTING, a netting extending fore and aft from the gunwale to a proper height up the rigging. Its use is, to prevent an enemy jumping aboard, on to the decks, in an engagement, &c.

NET WORK, BUCHANAN'S MACHINE FOR WEAVING.—The object of this newly invented machine, is to weave, expeditiously and without knots, any kind of net-work, and to allow the holes or meshes of the net-work to be enlarged or diminished according to the option of the operator.

Alexander Buchanan of Paisley, the inventor, adds another instance to the number of proofs that he has already given of his inventive genius, and ardent desire to improve the arts and manufactures of his native country. The machine in question consists of the following parts:—A B C D, fig. 1, represents a wooden stand upon which an iron frame, E F G H, is supported at each corner. In this frame there are seven wheels, 1, 2, 3, 4, 5, 6, 7, that pitch into each other. *i, k, l, m*, are continuations of the axis of the wheels numbered 1, 2, 5, 7. Upon the ends of the axis thus continued, circular pieces of wood, I, K, L, M, are fixed, a perspective view of which is given at fig. 2. The other wheels, 2, 4, 6, are introduced in order that when the machine is put in motion, those numbered 1, 3, 5, 7, may turn in the same direction, as it is necessary that the parts of the machine attached to the axis of these should do so. Into each of the circular woods, four grooves are cut, which allow

round, to show the grooves and shuttles in them. The grooves in this case are perpendicular to the wooden stand: it must be observed, however, that they lie horizontally when the shuttles are moved from one circular wood to another. This is necessary both for weaving the net-work properly, and for moving the shuttles with greater facility.

Fig. 4, represents one of the pins or bobbins. One end A, is considerably thicker than the other, and has a groove in it, which, when the pin is put on C, fig. 3, admits a spring D. This spring acts as a counterpart to a weight that is suspended from the ends of the threads, one of which proceeds from each pin to keep them from entangling with each other. Each of the shuttles is furnished with a spring, all of which must individually be so strong, that their aggregate strength will prevent the weight from drawing the threads off the pins, and at the same time sufficiently weak to allow the threads to come easily off the pins when drawn by the operator. Into the centre wheel 4, fig. 1, another pinches, having the same number of teeth; this wheel, which cannot be represented in the figure, is fixed to one end of the iron rod O, P, and at the other end of it a handle N is fastened. By this handle the machine is put in motion. The iron rods O, P, turn in two gudgeons, one of which is concealed by the iron frame, the other is represented at S.

Having now given a description of Mr. Buchanan's simple and ingenious machine, the method of using it will easily be comprehended. The pins having been previously filled with thread, or with any substance of which the net-work is to be wrought, are placed on the shuttles. The ends of the threads are then collected and tied together, after which they are put through a ring that is fastened on the top of the gudgeon S, fig. 1, and also through a hole T, in the sole or wooden stand; a weight is then suspended from the threads, the use of which, as was already mentioned, is to prevent them from entangling. It must be observed, however, that before the machine is put in motion, the shuttles occupy the proper grooves. This particular is illustrated in fig. 1, where the shuttles *a, b*, in the circular wood, I, occupy the second and fourth grooves; those of K, H, *c, d*, occupy the second and fourth; those of L, the first and third; and those of M, H, the second and fourth. The operator commences weaving the net-work by turning round the handle at N. The size of the meshes of the net-work, he enlarges or diminishes at pleasure, by turning the handle a greater or less number of times. By turning round the handle, the wheels in the iron frame, and the circular pieces of wood that are fixed to the axis of four of those wheels, are made to revolve; but when these pieces of wood are revolving, the threads which proceed from the shuttles of each are twisting round each other. The twist made by this movement is made tight by the operator, who puts a finger of his left hand between each pair of threads, and with his right hand inserts, horizontally, the clearer, which is a thin piece of wood, shaped like a paper cutter, between each pair of threads, drawing both his hand and clearer towards R, at which place it is prevented from going any farther by a knot. He then removes his hand, leaving the clearer to keep the twist tight, and crosses the threads to form the meshes. This is effected by moving the shuttles from one circular wood to another. This operation resembles, and effects exactly, the same object as the crossing of the pins in working lace. The shuttles of the middle circular woods are charged first. Those of the circular wood R, occupying the second and fourth grooves, are moved into the second and fourth of the circular wood L, while those of L are shifted into the first and third grooves of K. This movement forms half a mesh. The operator then turns round the handle the same number of times as formerly, to twist the other sides of the mesh that is already half formed, and also to twist the sides of other two meshes. This being done, and the twist made tight by the method just explained, the threads are again crossed, which is done as formerly by moving the shuttles from one circular wood to another. In the former instance, only the threads of the middle circular woods were made to cross each other; in this, however, the whole must be crossed, and, consequently, all the shuttles will require to be moved into I; those of I into K; and those of L are moved into M; while those of M are moved into L.

too shuttles, *a, b, c, d, e, f, g, h*, to slide out and in at the circumferences of the circular woods, but prevent them from coming out when drawn in a direction towards R. The shuttles, one of which is represented at fig. 3, consist of three parts. A, fig. 3, is that part which slides into the grooves B, the projecting part, and C, that which holds the pin or bobbin. The use of the grooves is to allow the shuttles to be moved from one circular wood to another in crossing the threads to form meshes of the net-work, and to afford an easy method of attaching them to the circular woods, after that they have been thus moved. In fig. 1, the circular woods are represented as turned half

By the first moving of the shuttles, those of the circular wood K were shifted into the corresponding grooves of L; and those of L were moved into the corresponding ones of K; so that by shifting them in the present instance, those that originally occupied the circular wood L, are moved into I; and those that originally occupied K are moved into M. This operation completes other two meshes. Thus, by twisting and crossing the threads, any quantity of net-work may be wove: the operator drawing more thread off the pirns as the former quantity is used.

In describing the method of using Mr. Buchanan's machine, we have called the substance with which the net work is wrought, thread. It is not to be understood, however, that this is the only substance which can be employed. It is a property of the machine that any kind of yarn or twine may be warped with it, so that by using fine yarn, and giving the handle a few turns, a texture may be wrought equally as fine as lace; and from the simplicity with which it may be wrought, we would strongly recommend the machine to the junior branches of families, who will find the using it to be an agreeable and profitable amusement.

NEUTRAL SALTS, a sort of salts neither acid nor alkaline, but partaking of the nature of both. See **ACID**, **ALKALI**, **SALTS**, &c.

NEUTRALIZATION. When two or more substances mutually destroy each other's properties, they are said to neutralize each other. Thus, in a proper combination of acid and alkaline substances, the acid and alkaline properties are destroyed.

NEWTON, DR. JOHN, a learned English mathematician, was born in Devonshire in 1622, and died in 1687, in the 66th year of his age. He was author of several works relating to different branches of the mathematical sciences, all of them exhibiting the hand of a complete master of his subjects.

NEWTON, SIR ISAAC, one of the greatest mathematicians and philosophers that any age or country ever produced, was born at Woolstrop, in Lincolnshire, on the 25th of December, 1642. He very early discovered strong traits of genius, which was improved by a liberal education; at twelve years of age he was put to the grammar school at Grantham, and in 1660 was entered a student in Trinity College, Cambridge.

He had not been long in college before he attracted the notice of the celebrated Dr. Barrow, and a sincere and lasting friendship took place between these two great men. Euclid's "Elements" were as usual first put into his hands, of which he soon made himself master, and his attention was then directed to Descartes' analytical method, and the optics of Kepler, in both of which he made several improvements, noting them down in the margins. He continued reading the works of the most celebrated authors till about the year 1664, and at this early age it was that he first laid the foundation of his new and admirable Method of Fluxions and Infinite Series. In the mean time, as mathematicians were then much engaged in improving telescopes, and grinding glasses for the purpose of constructing these instruments, he also set himself to work on the same subject, which led him to a repetition of Grimaldi's celebrated experiment with the prism. The vivid colours of the spectrum was to him, not only a source of delight and pleasure, but also of contemplation, particularly its oblong form, which, according to the principles then received, ought to have been circular; this phenomenon led him to other experiments, and finally to a new theory of light and colours, in which the heterogeneous nature of light was satisfactorily demonstrated.

It is impossible for us to follow this philosopher through the numerous and important discoveries and improvements with which he enriched science; suffice it to say, that he left scarce any subject unexplored. Analysis, astronomy, optics, mechanics, were alike the objects of his investigation, and experienced alike the powerful effects of his superior genius. In his private character, he was amiable and modest; he never talked, either of himself or others, so as to give the most malicious censurer the least occasion even to suspect him of vanity. He was candid and affable, and always put himself upon a level with his company; nor did any singularities, either natural or affected, distinguish him from other men. This great man died on the 20th of March, 1727, in the 85th year of his age, and

on the 28th of the same month was conveyed to Westminster Abbey, the pall being supported by the Lord Chancellor, the Dukes of Montrose and Roxburgh, and the Earls of Pembroke, Sussex, and Macclesfield. He was interred near the entrance into the choir on the left hand, where a stately monument is erected to his memory, with emblematical representations of some of his most important discoveries in the sciences, and an inscription highly honourable to his memory.

The NEWTONIAN Philosophy, or the doctrine of the universe, and particularly the heavenly bodies, their laws, affections, phenomena, &c. as taught and illustrated by Newton.

NEW TRIAL, in Law, is not granted upon nice and formal objections, which do not go to the real merits, nor where the scales of evidence hang nearly equal. It is generally upon some misdirection by the judge to the jury, in point of law, where a jury has found a verdict directly against evidence. It is also granted where damages have been given beyond the ordinary measure of justice, and where the party has been surprised by some evidence which he has subsequently the means of answering, but had not at the trial. It is always refused where the damages do not exceed £10.

NICKEL, a white metal, which, when pure, is both ductile and malleable, and may be forged into very thin plates, whose colour is intermediate between that of silver and tin, and is not altered by the air. It is nearly as hard as iron. Its specific gravity is 8.279, and when forged, 8.666. The species of nickel ores are its alloy with arsenic and a little sulphur, and its oxide. The first is the most abundant, and the one from which nickel is usually extracted. It is known to mineralogists by the German name of kupfernickel, or false copper, from its colour and appearance. It occurs generally massive and disseminated, its colour is copper-red of various shades. By the experiments that have been made, nickel in its pure state possesses a magnetic power. The effect of the magnet on it is little inferior to that which it exerts on iron; and the metal itself becomes magnetic by friction with a magnet, or even by beating with a hammer. Magnetic needles have even been made of it in France, and have been preferred to those of steel, as resisting better the action of the air. The nickel preserves its magnetic property when alloyed with copper, though it is somewhat diminished; by a small portion of arsenic it is completely destroyed. Nickel is fusible at 150 degrees of Wedgwood, and forms alloy with a number of metals. Nickel is found in Cornwall, and in some other counties of England; in Germany, Sweden, France, Spain, and several parts of Asia. The Chinese employ it in making white copper; and, in conjunction with copper and zinc, they manufacture it into various kinds of children's toys. Nickel gives a certain degree of whiteness to iron. It is used, with advantage, by some of the Birmingham manufacturers, in combination with that metal; and by others in combination with brass. If it were possible to discover an easy method of working nickel, there can be little doubt but it would be found very valuable for surgical instruments, compass needles, and other articles, since it is not, like iron, liable to rust. Oxide of nickel is used for giving colours to enamels and porcelain. In different mixtures it produces brown, red, and grass-green tints.

NICOTIANA, in Botany, *Tobacco*, a genus of the pentandria monogynia class and order. Natural order of *Luridæ*. *Solanææ* Jussieu. English tobacco seldom rises more than three feet in height, having smooth alternate leaves upon short foot-stalks; flowers in small loose bunches on the top of the stalks, of a yellow colour, appearing in July, which are succeeded by roundish capsules, ripening in the autumn. Sir Walter Raleigh, on his return from America, first introduced the smoking of tobacco into England. In the house in which he lived at Islington are his arms, with a tobacco plant on the top of the shield. It is remarkable that the name tobacco has prevailed over the original name, *petum*, in all the European languages, with very little variation, and even in Tartary and Japan. Tobacco is derived from the island Tobago. *Petum* is the Brazilian name.—Tobacco is sometimes used externally in unguents for destroying cutaneous insects, cleaning ulcers, &c. Beaten into a mash with vinegar or brandy, it has sometimes proved serviceable for removing hard tumours of the hypochondres.

NICTITATING MEMBRANE, in Comparative Anatomy, a thin membrane, chiefly found in the bird and fish kind, which covers the eyes of these animals, sheltering them from the dust, or from too much light, yet is so thin and pellucid that they can see through it.

NIDUS, among naturalists, a nest, or proper repository for the eggs of birds, insects, &c. wherein the young of these animals are hatched and nursed.

NIGELLA ROMANA. *Fennel Flower*. *The seeds*.—They have a strong, not unpleasant smell; and a subacid, somewhat unctuous disagreeable taste. They stand recommended as aperient, diuretic, &c. but, being suspected to have noxious qualities, should be used with caution.

NIGHT, that part of the natural day during which the sun is below the horizon; though the twilight, both in the morning and evening, is sometimes considered as forming part of the day.

NIHIL DICIT, a failure in the defendant to put in an answer to the plaintiff's declaration, &c. by the day assigned for that purpose.

NILOMETER, sometimes called *Niloscope*, an instrument used among the ancients to measure the height of the water in the river Nile, in its periodical overflowings. The measure of it was sixteen cubits, this being the height to which it must rise, in order to insure the fruitfulness of the country.

NIMBUS, in Antiquity, a circle observed on certain medals, or round the head of some emperors, answering to the circles of glory drawn around the images of saints.

NIPPERS, certain pieces of cordage used to fasten the cable to the messenger, or voyal, in a ship of war, when the former is drawn into the ship by mechanical powers applied to the latter. They are usually six or eight feet in length, according to the size of the cable, and five or six of them are commonly fastened about the cable and voyal at once; those which are farthest aft are always taken off as the cable approaches the main hatchway, and others are at the same time fastened on in the fore part of the ship, to supply their places, the boys of the ship receiving the ends to walk aft with them, and carrying them forward again when cast off from the cable.

NIPPER Men, persons employed to bind the nippers about the cables and voyal, and to whom the boys return the nippers when they are taken off. *Selvaer* NIPPERS are used, when from a very great strain the common nippers are not found sufficiently secure; selvaers are then put on and held fast, by means of tree nails.

NISI PRIUS, in Law, a commission directed to the judges of assize, empowering them to try all questions of fact issuing out of the courts of Westminster, that are then ready for trial by jury: the origin of which name is this: all causes commenced in the courts of Westminster-hall, are by course of the courts appointed to be tried on a day fixed in some Easter or Michaelmas term, by a jury returned from the county wherein the cause of action arises; but with this proviso,—*Nisi prius iusticiarum ad assisas capiendas venerint*; that is, unless before the day prefixed, the judges of assize come into the county in question, which they always do in the vacation preceding each Easter and Michaelmas term, and there try the cause. And then, upon return of the verdict given by the jury to the court above, the judges there give judgment for the party to whom the verdict is found.

NITRATES, compounds of nitric acid with the salifiable bases.

NITRE, the common name of the nitrate of potash, which is known by the name of saltpetre, and is found in the East Indies, in Spain, the kingdom of Naples, and elsewhere, in considerable quantities; but nitrate of lime is still more abundant. The greatest part of the nitre of commerce is produced by a combination of circumstances which tend to compose and condense nitric acid. This acid appears to be produced in all situations where animal matters are decomposed with access of air, and of proper substances with which it can readily combine. Grounds frequently trodden by cattle and impregnated with their excrements, or the walls of inhabited places where putrid animal vapours abound, such as slaughter-houses, drains, or the like, afford nitre by long exposure to the air. Artificial nitre-beds are made by an attention to the circumstances in which this salt is produced by nature. Its taste is penetrating; but the

cold produced by placing the salt to dissolve in the mouth is such as at first to predominate over the real taste. Seven parts of water dissolve two of nitre, at the temperature of sixty degrees; but boiling water dissolves its own weight. One hundred parts of alcohol, at a heat of 170 degrees, dissolve only 2.9. On being exposed to a gentle heat, nitre fuses; and in this state being poured into moulds, so as to form little round cakes, or balls, it is called *sal prunella* or *crystal mineral*. Many kinds of plants, which grow in soils favourable to the production of it, contain nitre: this is particularly the case with pelitory, borage, and the large sun-flower. Immense quantities of nitre are annually required for the purposes of war. From its constituting one of the most important substances in the composition of gun-powder, it has been found necessary to adopt artificial modes of procuring it. In several districts of the East Indies, there are certain places called *saltpetre grounds*. From these, large quantities of the earth are dug, and put into cavities through which water is passed. This brings away with it the salt that the earth contains, and this is afterwards separated from the water by boiling. It is extensively employed in metallurgy; it serves to promote the combustion of sulphur in fabricating its acid; it is used in dyeing; it is added to common salt for preserving meat, to which it gives a red hue; it is an ingredient in some frigorific mixtures, and it is prescribed in medicine as cooling, febrifuge, and diuretic; and some have recommended it mixed with vinegar, as a very powerful remedy for sea scurvy.

NITRIC Acid, is a compound of oxygen and azote, or nitrogen, in the proportion of twenty-five parts, by weight, of the latter to seventy-five of the former. It is one of the constituent parts of nitre or saltpetre, which from hence has its name; and, in a pure state, it is transparent and colourless, like water. By the action of light, however, it soon becomes yellow; and if exposed to the air, it emits yellow fumes, which even tinge the air of the same colour. To the taste it is extremely acid. It dyes the skin a yellow colour, which is very difficult to be removed, and is so corrosive as to destroy almost every substance into which it penetrates. If poured upon oils, it sets them on fire. With various bases it forms the compounds called *nitrates*. This acid, which has hitherto never otherwise been obtained than mixed with water, is chiefly known in commerce by the name of *aqua-fortis*. Its uses are various and important. The mode of obtaining it, in large manufactories, is by distilling a mixture of nitre and clay; but the acid thus procured being weak and impure, chemists, for nicer purposes, generally prepare it by distilling, in a glass apparatus, a proportion of three parts of nitre and one of spirit of vitriol. All kinds of metals are capable of being dissolved by nitric acid except gold and platina. For all practical purposes, nitric acid is obtained from nitrate of potash, from which it is expelled by sulphuric acid; and it is of considerable use in the arts, being employed for etching on copper; as a solvent of tin to form with that metal a mordant for some of the finest dyes; in metallurgy and assaying; in various chemical processes, on account of the facility with which it parts with oxygen and dissolves metals; in medicine, as a tonic, and as a substitute for mercurial preparations in syphilis and affections of the liver; as also in the form of vapour, to destroy contagion in all cases of fever. For the purposes of the arts it is used in a diluted state, and contaminated with the sulphuric and muriatic acids, by the name of *aqua-fortis*. Two kinds are sold in the shops, double *aqua-fortis*, which is about half the strength of nitric acid; simple *aqua-fortis*, which is half the strength of the double. A compound made by mixing two parts of the nitric acid with one of muriatic, known formerly by the name of *aqua regia*, and now by that of *nitro-muriatic acid*, has the property of dissolving gold and platina. On mixing the two acids heat is given out, an effervescence takes place, and the mixture acquires an orange colour. The *aqua-regia* does not oxidize gold and platinum, but causes their combination with chlorine. The nitrate of barytes, when perfectly pure, is in regular octahedral crystals, though it is sometimes obtained in small shining scales. It may be prepared by uniting barytes directly with nitric acid, or by decomposing the carbonate or sulphuret of barytes with this acid. Nitrate of strontian may be obtained in the same manner as that of barytes, with which it agrees in

the shape of its crystals, and most of its properties. Applied to the wick of a candle, or added to burning alcohol, it gives a deep red colour to the flame. On this account it is useful in the art of pyrotechny and in exhibitions at public theatres. Nitrate of lime abounds in the mortar of old buildings, particularly those that have been much exposed to animal effluvia, or processes in which azote is set free. The nitrate of ammonia possesses the property of exploding, and being totally decomposed at the temperature of 600 deg.; whence it has acquired the name of nitrum flammans.

NITROGEN, also called azote, a substance existing in great abundance, but is never found except in combination with some other body. Is a principal component part of the air which we breathe, which consists of 78 parts of nitrogen, and 22 of oxygen. It is accordingly here united with oxygen, and a certain portion of caloric and light. The nitrogen and oxygen of the atmospheric air may be separated, so that we may have the nitrogen by itself, but then only in a state of gas, and its properties are very different from those of the atmospheric air. Nitrogen gas will not support animal life. It is a little heavier than atmospheric air, elastic, and capable of expansion and condensation. It produces no change on vegetable colours, and, when mixed with lime water, does not make it milky, as does carbonic acid gas. Nitrogen gas and oxygen gas artificially mixed in proportions in which air is found in the atmosphere, have exactly the same properties as atmospheric air, which they become in every respect. All animal and vegetable substances contain a large portion of nitrogen. Different proportions of oxygen united with nitrogen produce compounds of very different properties: 78 parts of nitrogen and 22 of oxygen will produce atmospheric air. The same quantity of nitrogen with twice as much of oxygen make 100 of nitrous oxide. The same quantity of nitrogen and four times as much oxygen make nitric oxide. The same quantity still of nitrogen and eight times the quantity of oxygen, make nitrous acid. The same quantity of nitrogen, and ten times the quantity of oxygen, make nitric acid. Thus the only difference between atmospheric air, so necessary to life, and nitric acid, which would destroy us if received internally, consists in this, that the latter contains ten times as much oxygen as the former. Nitrous oxide, a gas chiefly remarkable for its intoxicating effects when inhaled, affords at public lectures much amusement to the spectators. It is obtained by distilling nitrate of ammonia. Nitrous oxide and nitrous acid are not of much importance. Nitrogen combines with chlorine, and is then dangerously explosive, and must be carefully and cautiously heated. It unites also with iodine.

NITROUS ACID, formerly called fuming nitrous acid, forms a distinct genus of salts, that may be termed nitrites.

NOBILITY, a quality that ennobles, and raises a person possessed of it above the rank of a commoner. The origin of nobility in Europe is referred to the Goths, who, after they had seized part of Europe, rewarded their chiefs with titles of honour, to distinguish them from the common people. In Britain the term nobility is restrained to the degrees of dignity above knighthood; but every where else nobility and gentility are the same. The British nobility consist only of five degrees, viz. duke, marquis, earl or count, viscount, and baron. In Britain these titles are conferred only by the king, and that by patent, in virtue of which it becomes hereditary. The privileges of the nobility are considerable, they are the king's hereditary counsellors, and are privileged from all arrests unless for treason, felony, breach of peace, condemnation in parliament, and contempt of the king. They enjoy their seats in the House of Peers by descent, and no act of parliament can pass without their concurrence; they are the supreme court of judicature, and even in criminal cases give their verdict upon their honour, without being put to their oath. In their absence, they are allowed a proxy to vote for them, and in all places of trust are permitted to constitute deputies, by reason of the necessity the law supposes them under, of attending the king's person; but no peer is to go out of the kingdom without the king's leave, and, when that is granted, he is to return with the king's writ, or forfeit goods and chattels.

NOBLE, a money of account containing six shillings and eight pence.

NOCTILUCA, a species of phosphorus.

NOCTURNAL ARCH, in Astronomy, the arch of a circle described by the sun, or a star in the night.

NOCTURNAL Semi Arch of the Sun, is that portion of a circle he passes over between the lower part of our meridian, and the point of the horizon wherein he rises; or between the point of the horizon wherein he sets, and the lower part of our meridian.

NOCTURNAL, or *Nocturlabium*, an instrument chiefly used at sea, to take the altitude or depression of some stars about the pole, in order to find the latitude and hour of the night. Some nocturnals are hemispheres or planispheres, on the plane of the equinoctial. Those commonly in use among seamen are two; the one adapted to the polar star, and the first of the guards of the little bear; the other to the pole star, and the pointers of the great bear.

This instrument consists of two circular plates applied to each other. The greater, which has a handle to hold the instrument, is about 2½ inches diameter, and is divided into twelve parts, agreeing to the twelve months, and each month subdivided into every fifth day; and so as that the middle of the handle corresponds to that day of the year wherein the star here regarded has the same right ascension with the sun. If the instrument be fitted for two stars, the handle is made moveable. The upper left circle is divided into twenty-four equal parts for the twenty-four hours of the day, and each hour subdivided into quarters. These twenty-four hours are noted by twenty-four teeth, to be told in the night. Those at the hour twelve are distinguished by their length. In the centre of the two circular plates is adjusted a long index, moveable upon the upper plate. And the three pieces, viz. the two circles and index, are joined by a rivet, which is pierced through the centre with a hole, through which the star is to be observed.

To use the Nocturnal:—Turn the upper plate till the long tooth, marked twelve, be against the day of the month on the under plate; then bringing the instrument near the eye, suspend it by the handle with the plane nearly parallel to the equinoctial; and viewing the pole star through the hole of the centre, turn the index about, till, by the edge coming from the centre, you see the bright star, or guard of the little bear, (if the instrument be fitted to the star); then that tooth of the upper circle, under the edge of the index, is at the hour of the night on the edge of the hour circle; which may be known without a light, by counting the teeth from the longest, which is for the hour twelve.

NODE, in Surgery, a tumour arising on the bones.

NODE, *Nodus*, in the doctrine of Curves, is a small oval figure, made by the intersection of one branch of a curve with another.

NONE, in Dialing, denotes a small hole in the gnomon of a dial, which indicates the hour by its light, as the gnomon itself does by its shadow.

NODES, in Astronomy, are the opposite points where the orbit of a planet crosses the ecliptic.

Ascending Node, is that where the planet ascends from the south to the north side of the ecliptic, which is denoted by the character ♄, and denominated *dragon's head*. **Descending Node**, is that where the planet descends from the north to the south side of the ecliptic, which is denoted by the character ♅, and is called the *dragon's tail*. The right line joining these two points, is called the *line of the nodes*. It appears by observation, that in all the planets the line of the nodes continually changes its place, its motion being in antecedenia, or contrary to the order of the signs, the particular quantity for which, in each planet, will be found under their several names.

NOLLE PROSEQUI, is used where the plaintiff will proceed no further in his action.

NO-MAN'S-LAND, a space in midships, between the after part of the belfry and the fore part of a boat, when she is stowed upon the booms, as in a deep waisted vessel.

NOMENCLATURE. The chemists of former times were unfortunate in the nomenclature which they adopted, there being no regular system, and the names given to chemical substances being frequently fanciful and often leading to error. In addition to this, chemists affected obscurity and mystery. To obviate these inconveniences, Lavoisier and the French che-

nists proposed, and successfully introduced, a chemical nomenclature, of which the basis is simplicity, and which is intended as far as possible to convey an idea of the composition of the substance expressed.

NOMENCLATURE, a catalogue of several of the most usual words in any language, with their significations, to facilitate the use of such words to those who are to learn the tongue.

NONAGESIMAL DEGREE, called also *Nid Heaven*, is the highest point, or 90th degree of the ecliptic, reckoned from its intersection with the horizon at any time.

NONAGON, a figure of nine angles and nine sides. The angle at the centre of a nonagon is 40° , the angle subtended by its sides 140° , and its area when the side is 1 = $\frac{1}{2}$ nat. tang. $70^\circ = 0.1518242$.

NONAPPEARANCE, a default in not appearing in a court of judicature. Attorneys subscribing warrants for appearing in court are liable to attachment and fine for nonappearance. If a defendant does not appear, and find bail upon a *scire facias* and rule given, judgment may be had against him.

NON COMPOS MENTIS, in Law, denotes a person not being of sound memory and understanding.

NON CLAIM, in Law, where a person has a demand upon another, and does not enforce his claim within a reasonable time, he is precluded by law from bringing his action to enforce it. Non claim is generally applied to the period of five years, after which a party is barred by a fine.

NONCONFORMISTS, the same with dissenters, of whom there are numerous separate congregations in these kingdoms.

NONES, *Nona*, in the Roman calendar, the fifth day of January, February, April, June, August, September, November, and December; and the seventh of March, May, July, and October, had six days in their nones; because these alone, in the ancient constitution of the year by Numa, had 31 days apiece, the rest having only 29, and February 30; but when Cæsar reformed the year, and made other months containing 31 days, he did not allot them six days of nones. See **CALENDAR**.

NON EST FACTUM, a plea where an action is brought upon a bond, or any other deed, and the defendant denies it to be his deed whereon he is impleaded. In every case where the bond is void, the defendant may plead *non est factum*; but where a bond is voidable only, as the law terms it, he must shew the special matter.

NON EST INVENTUS, signifies a sheriff's return to a writ, that the defendant is not to be found.

NONIUS, or **NUNEZ**, **PETER**, an eminent Portuguese mathematician and physician, was born at Alcazar, in Portugal, in 1497, and died in 1577, at the age of 80 years. From this author is derived the name of the instrument called the nonius, from his having described it in one of his works. The invention of it is, however, more commonly attributed to Vernier, by which name it is also sometimes called, and under which it is described in this work.

NON-NATURALS, in Medicine, so called because by their abuse they become the causes of diseases. The old physicians divided the non-naturals into six classes, viz. the air, meats and drinks, sleep and watching, motion and rest, the passions of the mind, the retentions and excretions.

NON-PROS, in Law, if the plaintiff neglects to deliver a declaration for two terms after the defendant appears, or is guilty of other delays or defaults against the rules of law in any subsequent stage of the action, he is adjudged not to pursue his remedy as he ought; and thereupon a non-suit or non-prosequitor is entered, and he is then said to be non pros'd.

NON-RESIDENCE, in Ecclesiastical matters, is applied to those spiritual persons who are not resident, but absent themselves for the space of one month together, or two months at several times in one year, from their dignities or benefices, which is liable to the penalties, by the statute against non-residence, 21 Henry VIII. c. 13. But chaplains to the king, or other great persons mentioned in this statute, may be non-resident on their livings; as they are excused from residence whilst they attend those who retain them.

NONSUIT, in Law, is where a person has commenced an action, and, at the trial, fails in his evidence to support it, or has brought a wrong action. The plaintiff pays costs, but may

bring another action for the same cause, which he cannot do after a verdict against him.

NORIA, an hydraulic machine, common in Spain, which raises water. This engine consists of a vertical wheel of 20 feet diameter, on the circumference of which are fixed buckets, or boxes, for the purpose of raising water out of wells, &c. communicating with the canal below, and emptying it in a reservoir above, placed by the side of the wheel. The buckets have a lateral orifice, to receive and discharge the water. The axis of the wheel is embraced by four small beams, crossing each other at right angles, tapering at the extremities, and forming eight little arms. This wheel is near the centre of the horse-walk, contiguous to the vertical axis, into the top of which the top beam is fixed; but near the bottom it is embraced by four little beams, forming eight arms, similar to those above described, on the axis of the water wheel. In the movement of the horse or mule, these horizontal arms acting as cogs, take hold, each in succession, of those arms, which are fixed on the axis of the water wheel, and keep it in rotation. This machine, nearly resembling the Persian wheel, throws up a great deal of water; but it has two defects: much of the water falls out of the buckets in their ascent, and a considerable portion of the water to be discharged falls into the reservoir just when the bucket is at its highest point of the circle. These inconveniences are both remedied by the Persian Wheel; which see.

NORMA VEL QUADRA EUCLIDIS, *Euclid's Square*, is a small constellation situated south of the Scorpion, and contains twelve stars, all below the fourth magnitude.

NORMAL, a perpendicular forming with another line a right angle.

NORMAN, a name given to a short wooden bar, thrust into one of the holes of the windlass in a merchantman, whereon to fasten the cable. It is only used when there is very little strain upon the cable.

NORTH, one of the four cardinal points.

NORTH-EAST PASSAGE. This navigation has been divided into three parts, and the advocates for it have endeavoured to shew that these three parts have been passed at different times, concluding from thence, that the whole taken collectively is practicable. These three parts are, 1. From Archangel to the river Lena; 2. From the Lena round Tschuket-skoi Noss (or the north-eastern promontory of Asia) to Kamschatka; and 3. From Kamschatka to Japan. With respect to the first part, no one has ever asserted that it has been performed in one voyage. From an account of the several voyages that have been made in these seas, it appears that there is a cape between the rivers Chalanja and Piasida, that has never yet been doubled. As to the second division, it has been affirmed, that a passage has been effected by several vessels which have at different times sailed round the northern extremity of Asia. But from the Russian accounts it is inferred, that it has been performed but once, viz. by one Deshneff, who, in 1648, is said to have doubled this formidable cape. Of the third, or remaining part, of this passage, no doubt can be entertained. The connexion between the seas of Kamschatka and Japan has been established by many voyages.

NORTH-West Passage, by Hudson's or Baffin's bay, into the Pacific ocean.

NORTHERN SIGNS, are those that are on the north side of the equator viz. Aries, Taurus, Gemini, Cancer, Leo, and Virgo.

NORTHING, in Navigation, is the difference of latitude which a ship makes in sailing towards the north.

NOSTOCK, the name of a vegetable substance, of a greenish colour, partly transparent, and of a very irregular figure. It trembles at the touch, like jelly, but does not melt like that. It is found in all, but most frequently in sandy soils, usually after rain in summer.

NOTARIAL ACTS, are those acts in the civil law, which require to be done under the seal of a notary, and are admitted as evidence in foreign courts.

NOTARY, in Law, is a person duly appointed to attest deeds and writings; he also protests and notes foreign and inland bills of exchange and promissory notes, translates languages, and attests the same, enters and extends ship's protests, &c.

NOTATION, in Arithmetic, the method of expressing, by means of certain characters, any proposed quantity. In the modern analysis, notation implies a method of representing any operation, and the judicious selection of proper symbols for this purpose is an important consideration, which every author who undertakes to write on this subject should particularly attend to. In the common scale of notation every number is expressed by means of the ten characters, 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, by giving to each digit a local as well as its proper or natural value, the discovery of which was perhaps one of the most important steps that has ever been made in mathematics, and does as much honour to its inventor as any other in the history of this science. With regard to the characters or digits, by which numbers are at this date universally expressed, they seem to be the same, with a very slight alteration, as those that were originally employed for that purpose: but their forms are not such as to indicate their origin, though some authors have discovered more ingenuity than judgment, by endeavouring to trace them to the Greek alphabet, and hence inferring, contrary to every evidence, a Grecian origin to our present system of notation. See the different arithmetical characters in the following engraving

I	II	III	IV	V	VI	VII	VIII	IX	X
1	2	3	4	5	6	7	8	9	10
1	2	3	4	5	6	7	8	9	10
1	2	3	4	5	6	7	8	9	10
1	2	3	4	5	6	7	8	9	10
1	2	3	4	5	6	7	8	9	10

1	2	3	4	5	6	7	8	9	10
1	2	3	4	5	6	7	8	9	10
1	2	3	4	5	6	7	8	9	10

NOTATION of the Hebrews, resembled, in a great measure, that of the Greeks above described; thus,

Instead of our units,..... 1, 2, 3, 4, 5, 6, 7, 8, 9,
The Hebrews used their letters,.... א, ב, ג, ד, ה, ו, ז, ח, ט.
For our tens, as..... 10, 20, 30, 40, 50, 60, 70, 80, 90,
They employed..... י, כ, ל, מ, נ, ס, ע, פ, צ.
For the hundreds they used..... ק, ר, ש, ת, י, כ, ל, מ, נ, ס, ע, פ, צ.

And for representing thousands, they had again recourse to their simple units, distinguishing them only by two dots, or

acute accents, thus $\ddot{א}$, or $\acute{א}$, expressed 1000; $\ddot{ב}$ 2000; $\ddot{ג}$ 10000, and so on.

NOTATION of the Greeks. These people had three distinct notations; the most simple of which was, by making the letters of their alphabet the representatives of numbers, α, 1; β, 2; γ, 3; and so on. Another method was by means of six capital letters, thus, Ι [iota for μία] 1; Π [πεντε] 5; Δ [τέτα] 10; Η [ήεκα] 100; Χ [χίλια] 1000; Μ [μύρια] 10000; and when the letter Π enclosed any of these, except Ι, it indicated the enclosed letter to be five times its proper value, as stated above; thus, [ΠΙ] represented 50; [ΠΒ] 500; [ΠΧ] 5000, and so on. This notation

was only used to represent dates and similar cases; for arithmetical purposes they had a more organized system, in which thirty-six characters were employed, and by these any number not exceeding 100000000, might be expressed, though in the first instance it appears that 10000, or a myriad, was the extent of their arithmetic.

Our digits,..... 1, 2, 3, 4, 5, 6, 7, 8, 9,
They expressed by the letters α, β, γ, δ, ε, ζ, η, θ.
For our tens, as..... 10, 20, 30, 40, 50, 60, 70, 80, 90,
They employed the letters ι, κ, λ, μ, ν, ξ, ο, π, ρ.
The hundreds were expressed by.. ρ, σ, τ, υ, φ, χ, ψ, ω, Ω.
And the thousands by α, β, γ, δ, ε, ζ, η, θ.

That is, they had recourse again to the characters of the simple units, which were distinguished by a small iota or dash placed below them; and with these characters a number under 10000 was readily expressed; and this, as we have

observed above, was, for some time, the limit of their arithmetic. Afterwards 10000, or a myriad, was represented by Μ, and any number of myriads by Μ placed under the number of them. Thus,

	α	β	γ
	Μ.	Μ.	Μ.
represented	10000	20000	130000, &c.

NOTATION of the Romans. This is still employed by us for dates and other similar purposes, and is too well known to require a very minute description. The Roman numerical characters are seven in number; viz. I. one; V. five; X. ten; L. fifty; C. a hundred; D. or ΙϞ. five hundred; M. one thousand; this last number is also sometimes expressed by DD, or by CIϞ. And by the various combinations of these characters, any number whatever might be expressed, as in the following table:—

1 = I.	
2 = II.	{ As often as any character is repeated,
3 = III.	{ so many times is its value repeated.
4 = IV.	{ A less character before a greater, dimin-
5 = V.	{ ishes its value by the less quantity.
6 = VI.	{ A less character after a greater, in-
7 = VII.	{ creases its value by the less quantity.
8 = VIII.	
9 = IX.	
10 = X.	
11 = XI.	
40 = XL.	
50 = L.	
60 = LX.	
100 = C.	
500 = D. or ΙϞ.	{ For every Ϟ added, this becomes
1000 = M. or CIϞ.	{ ten times as much.
6000 = ΙϞϞ. or V.	{ For every ϞϞ, set one at each end,
	{ this becomes ten times as much.
60000 = ΙϞϞϞ. or V.	{ A line over any figure increases it
	{ 1000 fold.
6000 = VI.	
10000 = X.	or CCIϞϞ.
60000 = ΙϞϞϞ.	
60000 = LX.	
100000 = M.	or CCCCIϞϞϞ.
1000000 = MM.	or CCCCΙϞϞϞϞ.

NOTATION, in Music, the manner of expressing or representing by characters, all the different sounds used in music.

NOTE, a minute or short writing containing some article of business; in which sense we say promissory note, note of hand, bank note, &c.

NOTE, Bank. The paper currency of any bank, as of the Bank of England, that of Scotland or Ireland, or of any provincial or private bank.—This currency is known as bank-paper, or bank-note, and this note is usually printed on a particular sort of paper, from an engraved plate. The consideration of every such engraving, but for the sake of alphabetical reference, would in this Dictionary belong to the word engraving or printing: it falls most naturally under the word NOTE. But as preliminary explanations, we shall here define accurately the two species of engraving that have been heretofore employed in printing bank-notes:—First, then, there is employed *engraving in Creux*, or copper-plate engraving, where the line or figure intended to be printed is cut down into the copper. This line, in printing, is filled with the ink, and the intermediate surface being cleaned off after the plate has been charged, contains of course no ink, and leaves the paper white. This mode of printing is called *copper-plate printing*. Secondly, *engraving in Relief*, wherein the lines or figures, intended to be printed on the paper, are left standing on the plate, the intermediate parts being cut away. In this case, which is exactly the converse of the former, the ink is applied to the surface only of those raised lines or figures, and from them it is transferred to the paper; the intermediate excavated parts containing no ink, and therefore leaving the paper white. This mode of printing is called *surface printing*, and is the same as

cured to the other branches of the Paper Currency, the least effect upon the protection of parliament, the Bank of England Note.

It has been already observed, that the Compound Plate is an application of certain principles illustrated by Sir J. B. Reade in his book on the Metallic Currency, not to be refuted without immediate detection. It is curious to see the applicability of these same principles to the security of coin and paper currency. That which is the coin in one case, becomes the plate for the printing from in the other, the delicate and perfect union of colours, which will be thus effected on the paper, produces a similar, and so positive a test of originality, by its coincidence of colour, as that which the union of the metals themselves in the coin: but this will be better understood by a plate.

Plates are made of two metals, of which one must be copper, or other metal at least as strong. The design is drawn on the brass plate; the parts in which it is to introduce the second colour, are then cut out in delicate filigree. A second plate is then combined with the first, by a process peculiar to this sort of workman, parts of which are fitted most accurately into all the parts of the brass plate; and, indeed, the fineness of the work by hypothesis such, that the combination can only be effected by this peculiar mode of uniting the two metal plates, which are then engraved as one; and for printing; they are pressed of peculiar construction, so that they may be made to receive a different coloured ink on each plate, and then to print whatever work may be engraved, or otherwise upon them, in two colours at one impression.

In the Specimen Plate before us, all those parts of the plate which bear the red colour, as my own name, that of the author, and the various crescents or devices, may be made of the second colour workmanship cut out in filigree in the plate, while the black ground exhibits the second colour united with the first. By this means, the most beautiful and delicate junction of colour is effected. The finest effect is formed of various portions of different colours, as if produced in one colour by the stroke of an engraver's plate; a single point may be found of the two perfect union; and the most beautiful and correct effect of colour and complicated variety of forms may be as utterly to defy imitation by any of the ordinary modes of printing in two colours. In fact, if sufficient art be used, in combining this tissue of extremely nice and colour over the whole surface of the Compound Plate, the whole of the work on the note must be produced by one simultaneous operation of the forger, and cannot be the American note, be imitated in any way that produces a repetition of impressions.

It is only in conclusion to add, that we will give one hint to any artist who, by two impressions of printing colours, shall produce the fellow of Whiting and Brampton Plate, as engraved and printed for Dr. Hutton's Dictionary of Mechanical Science.

N, in Music, are characters which by their various situation on the staves, indicate the duration as well as the acuteness of the several sounds of a composition.

NULLITY, the general issue or plea of a defendant, in an action or prosecution; as also in an action of trespass upon the case for deceits and wrongs.

NOTICE, in Law, is the making something known of which a person is or might be ignorant before, and it produces divers effects.

NOUN, in Grammar, a part of speech which signifies things in relation to time; as a man, &c.

NOMEN, in the Civil Law, a term used for the constitution of an emperor, as of Justin, Tiberius, Leo, and more particularly that of Justinian.

ASSIGNMENT, or **NEW ASSIGNMENT**, a term in law pleadings of trespass, where the form of the declaration is general, the defendant pleads in bar a common justification to which the plaintiff replies by stating, that he is not liable as well for a certain other trespass which he

states with more particularity, as for that which is justified,—this is called a new assignment.

NOVEMBER, the eleventh month in the Julian year, but the ninth in the year of Romulus, beginning with March, whence its name. In this month, which contains thirty days, the sun enters the sign Sagittarius ♐, usually about the twenty-first day of the month.

The *Kalendar of Animated Nature* for November, round London, informs us, that the buck grunts, the golden plover appears, snails and slugs bury themselves, greenfinches flock, the winter moth and the common flat-body moth appear in gardens about the end of the month.

That of *Vegetable Nature*, shows a few accidental annual plants in flower, according to the temperature of the season. The laurustinus and the calicantus præcox are in flower, as are some primroses.

In the *Kitchen Garden*, are sown short-topped radishes on a warm border, and pease and beans; celery, endive, artichoke, and seakale, are protected; potatoes left in the ground, are taken up as wanted. Outstanding edible roots are covered with litter or leaves; cauliflowers by hoops and mats.—Perennials are propagated, and any thing to be transplanted, and that has been omitted in October, must now be removed.

In *Routine Culture*, all operations on the earth, excepting digging and trenching, must be performed only in dry weather. Dress artichoke and asparagus beds; take up endive, broccoli, and cauliflower, and lay them flat in dry ground. Weed all seedling crops. Dig, trench, and manure. Destroy insects, and fill the icehouse if you can.

In the *Hardy Fruit Department*, plant trees in dry weather, stake and mulch both root and stem, especially tall standards of the pithy wooded sorts. Prune vines, dig, dress, and prune hardy fruit trees: the nectarine, peach, and apricot, should be deferred till spring. Examine the fruit room, and clear it of all decaying fruits.

In the *Culinary Hot-house Department*, glass-case without artificial heat, sow small salads, and pease and beans, to transplant or remain. Attend to air, and removing decayed leaves. Transplant lettuces from the cold frames, to force them forward; begin to force asparagus, and build mushroom-beds.

In the *Flower Garden open ground Department*, plant dried roots of border flowers; transplant biennials, if the weather is fine; protect tender roots by litter and leaves, or tan and ashes. Land up trees with mats or straw, covered with nets. In the routine culture, collect earths, composts, and manures.

In the *Flower Garden Hot-house Department*, glass-case without artificial heat; take care of alpine, annuals, and perennials intended for forcing. Guard against damps by excluding air charged with heavy moisture. In the hot-beds and pits, go on forcing all manner of flowering shrubs, bulbs, and perennial plants. Blow Dutch roots in water glasses. In the greenhouse, the temperature must be 42° at a medium. In the dry stove, the temperature should be 45° or 50° at a maximum. In the dark and moist stove, from 65° to 70° at a maximum.

In the *Pleasure Ground and Shrubbery*, plant deciduous trees and shrubs of the hardier kind in dry weather; prune and cut hedges; protect magnolias, Chinese rose-trees; roll, mow, and sweep turf. Prepare for planting, by levelling, digging, trenching, &c.

In the *Nursery Department*, fruit trees must be planted only in mild weather; after the middle of November, it is not proper to meddle with fruit trees till February. Ornamental trees and shrubs may now be planted; the larger seeds of forest trees may be sown: cones, acorns, masts, nuts, keys, and berries for immediate sowings, may now be gathered.

PERMANENT PLANTATIONS and **Park Scenery** trees should now be planted in temperate weather; deciduous trees should be pruned, thinned, or felled, according to circumstances. Dead fences of every description, repair or erect; but never build walls in December or January.

NUCLEUS, the *Kernel*, is used by Hevelius, and some other astronomers, for the body of a comet, which others call its head, as distinguished from the tail or beard. Nucleus is also used by some writers for the central parts of the earth and other planets, which they suppose firmer, and separated from the other parts, as the kernel of a nut is from the shell.

calling the first three, hundreds and units; the next three, thousands; the next three, millions; the next three, billions, the next three, trillions, &c.

NUMERATION, or *Notation*, the art of expressing in characters any number proposed in words; or of expressing in words any number proposed in characters.

NUMERATOR of a *Fraction*, that number which stands above the line, and shews how many parts the fraction consists of; as the denominator represents the number of parts into which the unit is supposed to be divided.

NUMERICAL, or **NUMERAL**, something that relates to number.—*Numerical Algebra*, are those cases in which numbers are employed, in contradistinction to *Literal Algebra*, or that in which the letters of the alphabet are made use of.

NUMIDA, the *Pintado* or *Guinea Hen*, in Natural History, a genus of birds of the order gallinæ, whose native territory is Africa. It is gregarious, having been often seen in numerous flocks, but now extremely common in this country. The female lays many eggs, and secreting her nest, sometimes will suddenly appear with a family of twenty young ones. It is a bird of harsh sound, which it almost perpetually utters. The flesh of the young birds is valued, and its eggs are thought preferable to those of the common hen.

NUNCIO, or **NUNTIO**, an ambassador from the pope to some Catholic prince or state.

NUNCUPATIVE WILL, denotes a last will or testament, only verbally, and not in writing.

NUPHAR, in Botany, is the yellow water lily, from the flowers of which was anciently prepared a cooling drink. The Turks still make sherbet from these flowers, which give a kind of bitter-almond flavour to the liquor in which they are infused. Class Polyandria, order Monogynia.

NURSERY, a piece of land for raising and propagating trees and plants to supply the garden and other plantations. In a nursery for fruit trees, the following rules are to be observed. 1. That the soil should not be better than that in which the trees are to be planted, when removed. 2. It is highly necessary that it be fresh. 3. It ought neither be too wet, nor too dry, but rather of a middling nature, though of the extremes dry is preferred. 4. It must be enclosed in such a manner that neither cattle nor vermin may come in; and to exclude hares and rabbits. 5. The ground being enclosed, should be carefully trenched two feet deep, in August. In trenching the ground, cleanse it from the roots of all noxious weeds. 6. The season being come for planting, level down the trenches about the beginning of October, and then lay out the ground into quarters, which may be laid out in beds for a seminary, in which you may sow the seeds or stones of fruit. 7. And having provided yourself with stocks, the next year proceed to transplant them: draw a line across the ground, and open a number of trenches exactly straight; then take the stocks out of the seed-beds; in doing which you should raise the ground with a spade, in order to preserve the roots as entire as possible; prune off the very small fibres; and if there are any that have a tendency to root directly downwards, such roots should be shortened. Then plant them in the trenches, if they are designed for standards, in rows three feet and a half or four feet from each other, and a foot and a half distant in rows; but if for dwarfs, three feet row from row, and one foot in the row, will be a sufficient distance. These plants should not be headed or pruned at top. If the winter should prove very cold, lay some mulch on the surface of the ground near their roots, taking care not to let it lie too thick near the stems of the plants, and to remove it as soon as the frost is over. In the summer season destroy the weeds, and dig up the ground every spring between the rows. See **GRAFTING**. As to timber trees, nurseries should be made upon the ground intended for planting, where a sufficient number of the trees may be left standing, after the others have been drawn out to plant in other places.

NUT, in Vegetable Physiology, is a hard and bony seed, not opening by valves, but usually consisting of one cell and kernel.

NUTATION, in Astronomy, is a tremulous motion of the earth's axis, through which its inclination to the plane of the ecliptic undergoes some changes. This phenomenon was first observed by Dr. Bradley, who published an account of his

discovery in 1717. The period of these variations is nine years.

NUTGALLS, are excrescences formed on leaves of the oak by the puncture of an insect, which deposits an egg on them. The best are the Aleppo galls of commerce, imported for the use of dyers, calico printers, &c.

NUTMEG, the kernel of a large fruit, not unlike the peach, the produce of the *MIRISTICA*, which see. The nutmeg is separated from its investient coat, the mace, before it appears in commerce. The nutmeg, as we receive it, is of a roundish or oval figure, of a tolerably compact and firm texture, but easily cut with a knife, and falling to pieces on a smart blow. Its surface is not smooth, but furrowed with a number of wrinkles, running in various directions, though principally longitudinally. It is of a greyish brown colour on the outside, and of a beautiful variegated hue within. It is very unctuous and fatty to the touch when powdered, of an extremely agreeable smell, and of an aromatic taste, without the heat that attends that kind of flavour in most of the other species. The largest, heaviest, and most unctuous are to be preferred, such as are the shape of an olive, and of the most fragrant smell.

NUX VOMICA, the seed of the officinal strychnos, a native of the East Indies. It is about an inch broad, and nearly a quarter of an inch thick, covered with a kind of woolly matter; internally it is tough and hard, like horn, to the taste extremely bitter, but having no remarkable smell; it consists chiefly of a gummy matter, the resinous part being very inconsiderable. *Nux vomica*, reckoned amongst the most powerful poisons of the narcotic kind, proves fatal to dogs in a very short time. Loureiro relates that a horse died in a quarter of an hour after taking an infusion in wine of the seeds in a half-roasted state. It is employed to stupify fishes in a fish pond, when they come to the surface and are easily taken.

NYMPH, among naturalists, that state of winged insects between their living in the form of a worm and their appearing in the winged or most perfect state.

NYL GHAU, in Zoology, an animal between the deer and the ox, swift of foot, and remarkably strong. The first pair were sent from Bombay to England in the year 1767, as a present to Lord Clive.

NYMPHÆA, **WATER LILY**, a genus of the polyandria monogynia class and order, of which there are six species: 1. and 2. The lutea and alba, or yellow and white water lilies; natives of Britain, growing in lakes and ditches. Linnæus tells us that swine are fond of the leaves and roots of the former, and that the smoke of it will drive away crickets and battæ, or cockroaches, out of houses. The roots of the second have an astringent and bitter taste, and are used to dye dark brown. 3. The lotus, with heart-shaped toothed leaves, a plant thought peculiar to Egypt, is mentioned by Herodotus and Savary, as growing in the rivulets, and on the sides of the lakes; there are two sorts or varieties of this plant, the one with a white the other with a bluish flower. The calyx blows like a large tulip, and diffuses a sweet smell resembling that of the lily. The first species produces a round root like that of a potato, and the inhabitants of the banks of the lake Menzall feed upon it. 4. In the East and West Indies grows a species of this plant, named nelumbo by the inhabitants of Ceylon; the flowers, large and flesh coloured, consist of numerous petals, disposed in two or more rows; and are held sacred among the Hindoos. It is divided into several distinct cells, which form so many large round beds upon the surface of the fruit, each containing a single seed.

NYMPHÆA ALBA, and **LUTEA**. These are aquatics, and scarcely any plant is more deserving of our attention. The fine appearance of the foliage floating on the surface, which is interspersed with beautiful flowers, will render any piece of water very interesting: it should also be observed, that gold fish are found to thrive best when they have the advantage of the shade of these plants. It is difficult in deep water to make them take root, being liable to float on the surface, in which state they will not succeed. But if the plants are placed in some strong clay or loam, tied down in wicker baskets, and then placed in the water, there is no fear of their success: they should be placed where the water is sufficiently deep to inundate the roots two feet, or a little more.

diameter, in the proportion of 331 to 332: that is to say, the polar diameter is 7900 miles, and the equatorial diameter 7924 miles.

OBLATI, secular persons who bestowed themselves and estates on some monastery, for which they were admitted as lay brothers.

OBLATIONS; these primarily denoted things offered to God either through the church, or the priests. The term is now used in a less restricted sense.

OBLIGATION, a bond containing a penalty, with a condition annexed, either for payment of money, performance of covenant, or the like.

OBLIGER, in Law, he who enters into an obligation; as obligee the person to whom it is entered into.

OBLIQUE, in Geometry, something slant, or inclining from the perpendicular, as *oblique* ascension, *oblique* circle, *oblique* descension, *oblique* planes, in Dialing; *oblique* sailing, in Navigation. See these several words.

OBLONG, in Geometry, a figure that is longer one way than another, as one of the columns of this page of paper; which takes the form of a parallelogram.

OBOLARIA, a genus of plants belonging to the didynamia class, and ranking under the 40th order, Personata.

OBOLUS, in Antiquity, an ancient Athenian coin, worth a penny farthing. In medicine, *obolus* signifies a weight of ten grains, or half a scruple. Among the Sicilians, *obolus* denotes a weight of one pound.

OBRINE, knights of a military order, instituted in the 13th century by Conrad.

OBSERVATION, in Astronomy and Navigation, denotes the measuring with some proper instrument for the purpose, the angular distance, altitude, &c. of the sun, moon, or other celestial body.

OBSERVATORY, **OBSERVATORIUM**, a place destined for observing the heavenly bodies; or a building usually in form of a tower, raised on some eminence, and covered with a terrace for making astronomical observations. The more celebrated observatories are, 1. The Greenwich Observatory, or Royal Observatory of England, was built in 1676, by order of Chas. II. at the solicitation of Sir Jonas Moore and Sir C. Wren, and furnished with the most accurate instruments by the same, particularly a noble sextant of seven feet radius, with telescopic sights. The province of observing was first committed to Flamsteed, a man who seemed born for the employment. For fourteen years, with unwearied pains, he watched the motions of the planets, and particularly those of the moon, as was given him in charge; that a new theory of that planet being found, exhibiting all her irregularities, the longitude might thence be determined. In the year 1690, having provided himself with a mural arch of seven feet diameter, well fixed in the plane of the meridian, he verified his catalogue of the fixed stars, (which hitherto had depended altogether on the distances measured with the sextant,) after a new and very different manner, viz. by taking the meridian altitudes, and the movements of culmination, or the right ascension and declination. With this instrument he was so pleased, that he laid the use of the sextant almost wholly aside; and in this way was the astronomer royal employed for thirty years; in the course of which time nothing had appeared in public worthy so much expense and preparation; so that the observer seemed rather to have been employed for his own sake, and that of a few friends, than for the public; though it was notorious the observations that had been made were very numerous, and the papers swelled to a great bulk. This occasioned Prince George of Denmark, in 1704, to appoint certain members of the Royal Society, viz. the Hon. Fr. Roberts, Sir C. Wren, Sir Isaac Newton, Dr. Gregory, and Dr. Arbuthnot, to inspect Flamsteed's papers, and select such as they should think fit for the press, purposing to print them at his own expense; but the prince dying before the impression was half finished, it lay still for some time; till at length it was resumed by order of Queen Anne, and the care of the press committed to Dr. Arbuthnot; and that of correcting and supplying the copy to Dr. Halley. Such was the rise and progress of the "Historia Cœlestis;" the principal part whereof is the catalogue of fixed stars, called also the Greenwich Catalogue. Flamsteed was

succeeded by Dr. Halley; and Dr. Halley, in 1742, by Dr. Bradley, so deservedly celebrated for his discovery of the aberration of the stars, and the nutation of the earth's axis, after Dr. Bradley, the appointment was, in 1762, conferred upon Mr. Bliss, who was succeeded in 1785 by Dr. Maskelyne, the late worthy astronomer royal; upon whose demise, in 1811, this important office was conferred upon Mr. Pond.

The Greenwich observatory is found, by very accurate observation, to lie in $51^{\circ} 28' 30''$ north latitude.

2. The French Observatory, built by Louis XIV. in the Fauxbourg St. Jacques, Paris, is a very singular, but withal, a very magnificent building. It is eighty feet high, and at the top there is a terrace. It is here M. de Lahire, M. Cassini, &c. have been employed. This observatory was begun in 1664, and finished in 1672. The difference in longitude between this and Greenwich Observatory is $2^{\circ} 20' 15''$ each. In the Paris Observatory is a cave, or cellar, of one hundred and seventy feet descent, for making various experiments, particularly such as relate to congelations, refrigerations, indurations, conservations, &c. And in this cave there is a thermometer of M. de Lahire, which is always at the same height, indicating the temperature of the place to be always the same.

3. Tycho Brahe's Observatory in the little island Ween, or the Scarlet Island, between the coasts of Schonen and Zealand in the Baltic, was erected, and furnished with instruments, at his own expense; and was called by him Uraniburgh. In this place he spent twenty years in observing the stars.

We may enumerate here some other observatories, as that of Pekin, erected by a late emperor of China in his capital, upon the recommendation of the Jesuit missionaries; and that of the Bramins at Benares, in the East Indies, of which we give an engraving, (see plate OBSERVATORY) representing and illustrating several particulars, as in the following description:—

The observatory at Benares, built by order of the emperor Akbar, was once a magnificent structure; the lower part of it is now, however, converted into stables; the court yards and apartments are still spacious. It stands on the banks of the Ganges, and the summit is approached by a staircase leading to a large terrace, where numerous instruments still remain in great preservation, stupendously large, immoveable from the spot, and built of stone, some of them being upwards of twenty feet in height. Their graduation is very exact.

The situation of the two large quadrants, marked A in the plate, whose radius is nine feet two inches, by their being at right angles with a gnomon at 25° elevation, shew the stability and excellence of the architecture. The three sights on this gnomon occupy a space of $3\frac{1}{2}$ feet, and they are perfectly true. The quadrants, 20 feet in diameter, are built in perpendicular ovals, that follow the meridian of the place. The arcs of those quadrants are graduated into nine parts, and each of these again into ten parts $= 90^{\circ}$ in all.

Figure A is properly an equinoctial sun-dial, that expresses solar time by the shadow of a gnomon upon two quadrants, one east and the other west of it. Fig. B is an instrument for determining the exact hour of the day by the shadow of a gnomon, which stands perpendicular to, and is in the centre of, a flat circular stone, supported in an oblique position by four upright stones and a cross piece, so that the shadow of the gnomon, which is a perpendicular iron rod, is thrown upon the division of the circle described on the face of the flat circular stone.

Figure C is a brass circle, about two feet diameter, moving vertically upon two pivots between two stone pillars, having an index or hand turning round horizontally on the centre of this circle, which is divided into 300 parts. This is in fact an azimuth instrument; since its use is to measure on what point of the horizon any celestial body may rise or set.

Figure D consists of two circular walls, the outer one forty feet diameter and eight feet high, and the inner wall, half that height, appears to be a parapet, from which to observe the divisions on the upper circle of the outer wall. Both circles are divided into 300 equal parts, each divided into 20 lesser divisions. In this inner circle is a pillar exactly in its centre, in which a perpendicular rod has been once placed.

Figure E is a small equinoctial sun-dial, constructed similarly to fig. A.

The principal instruments for a fixed observatory are, a large fixed quadrant or a circular divided instrument, chiefly for measuring vertical angles; a transit instrument; an equatorial instrument; a chronometer, or regulator; one or more powerful telescopes; a fixed zenith telescope, and a night telescope. The quadrant or quarter of a circle, divided into 90 degrees, and each degree subdivided into minutes or smaller parts, has been made of various sizes; some of them having a radius even of eight or nine or more feet in length. When those quadrants do not exceed one or two, or at most three, feet, in radius, they are generally fixed upon their particular stands, which are furnished with various mechanical contrivances, that are necessary to place the plane of the quadrant perpendicular to the horizon, and for all the other necessary adjustment. But large quadrants are fixed upon a strong wall. See **QUADRANT**.

The transit instrument consists of a telescope of any convenient length, fixed at right angles to a horizontal axis, which axis is supported at its two extremities; and the instrument is generally situated so that the line of collimation of the telescope may move in the plane of the meridian. The use of this instrument is to observe the precise time of the celestial bodies' passage across the meridian of the observatory. See **TRANSIT INSTRUMENT**.

To adjust the Clock by the Sun's transit over the Meridian. Note the times by the clock when the preceding and following edges of the sun's limb touch the cross wires. The difference between the middle time and 12 hours shews how much the mean or time by the clock is faster or slower than the apparent or solar time for that day: to which the equation of time being applied, will shew the time of mean noon for that day, by which the clock may be adjusted.

Astronomical or equatorial sector, an instrument for finding the difference in right ascension and declination between two objects, the distance of which is too great to be observed by the micrometer, was invented by Graham. See **EQUATORIAL**.

Equatorial or Portable Observatory, an instrument designed to answer a number of useful purposes in practical astronomy, independently of any particular observatory; it may be made use of in any steady room, and performs most of the useful problems in the science. The principal uses of this equatorial are:

1. To find the meridian of one observation only: for this purpose elevate the equatorial circle to the co-latitude of the place, and set the declination semi-circle to the sun's declination for the day and hour of the day required; then move the azimuth and hour circles both at the same time, either in the same or contrary directions, till you bring the centre of the cross hair in the telescope exactly to cover the centre of the sun; when that is done, the index of the hour circle will give the apparent or solar time at the instant of observation; and thus the time is gained, though the sun is at a distance from the meridian; then turn the hour circle till the index points precisely at 12 o'clock, and lower the telescope to the horizon, in order to observe some point there in the centre of your glass, and that point is your meridian mark found by one observation only; the best time for this observation is three hours before or three hours after twelve at noon.

2. To point the telescope on a star though not on the meridian, in full day-light. Having elevated the equatorial circle to the co-latitude of the place, and set the declination semi-circle to the star's declination, move the index of the hour circle till it shall point to the precise time at which the star is then distant from the meridian, found in tables of the right ascension of the stars, and the star will then appear in the glass.

Besides these uses peculiar to this instrument, it is also applicable to all the purposes to which the principal astronomical instruments, viz. a transit, a quadrant, and an equal altitude instrument, are applied.

Of all the different sorts of chronometers or time-keepers, a pendulum clock, when properly constructed, is undoubtedly capable of the greatest accuracy; therefore, such machines are most recommendable for an observatory. The situation of this clock must be near the quadrant, and near the transit instrument; so that the observer, whilst looking through the telescope of any of those instruments, may hear the beats of the clock, and count the seconds.

A pretty good telescope placed truly vertical in an observatory, is likewise a very useful instrument, as the aberration of the stars, and latitude of the place, may be observed and determined by the use of such an instrument, with great ease and accuracy. See **TELESCOPE**.

The night telescope is a short telescope, which magnifies very little; but it collects a considerable quantity of light, and has a very great field of view; it therefore renders visible several dim objects, which cannot be discovered with telescopes of considerably greater magnifying powers; and hence it is very useful for finding out nebulae, or small comets, or to see the arrangement of a great number of stars in one view.

The principal instruments that are at present used for marine astronomy, or for the purposes of navigation, are, that incomparably useful instrument called Hadley's sextant or quadrant, or octant; a portable chronometer; and a good telescope.

OBSIDIAN, a volcanic glass, resembles lumps of black glass. Its surface is smooth, it is hard, and strikes fire with steel. It is common in the neighbourhood of volcanoes, and in some basalts, probably the products of volcanic fires now extinguished. In Lipari, one of the volcanic isles, the mountain *del Castagna*, according to Spalanzani, is wholly composed of volcanic glass, which appears to have flowed in successive currents like streams of water falling with a rapid descent, and suddenly frozen. This glass is sometimes compact, and sometimes porous and spongy. Obsidian appears to be lava suddenly cooled; if a mass of lava or basalt be exposed to the heat of a glass furnace, it melts into a shining black or greenish black glass. Numerous veins of obsidian are said to intersect the cone of Mount Vesuvius, and serve as a cement to keep together the loose materials of which it is composed. Obsidian is sometimes ground and polished, and used for mirrors.

OBSIDIANUS LAPIS, in the natural history of the ancients, was the name of a stone sometimes called *China marble*. It is black, smooth, hard, difficult to cut, capable of receiving a fine polish, and was used among the Greeks for the making of reflecting mirrors. In Peru, at the time of its conquest by the Spaniards, the inhabitants used it for mirrors, and in Europe it has been converted into reflectors for telescopes.

OBSTRUCTION, in Medicine, such an obturation of the vessels as prevents the circulation of the fluids, whether of the food and vital, or of the morbid and peccant kind, through them.

OBTUSE, literally implies any thing blunt or dull, in contradistinction to acute, sharp, or pointed.

OBTUSE Angle, Angular Section, Cone, Hyperbola, &c.

OCCATION. In ancient husbandry this term was nearly synonymous with our modern harrowing, though the instrument employed was a kind of rake.

OCCIDENT, in Astronomy and Geography, is the same as westward, or point of the horizon where the sun sets. A planet is said to be occident when it sets after the sun.

OCCIDENT, Equinoctial, that point of the horizon where the sun sets when he crosses the equinoctial, or enters the sign Aries or Libra.

OCCIDENT, Estival, that point of the horizon where the sun sets at his entrance into the sign Cancer.

OCCIDENT Horizon. See **HORIZON**.

OCCIDENT, Hybernal, that point where the sun sets when he enters the sign Capricorn.

OCCULT LINE, in Geometry, a dry or obscure line, which is drawn as a necessary part of the construction of a figure or problem, but which is not intended to appear after the plan is finished.

OCCULT, something hidden or secret; as the occult qualities of bodies.

OCCULTATION, the obscuration of a planet or star by the interposition of the moon, or other planet, between it and our eye.

OCCUPANCY, in Law, the taking possession of things which before belonged to nobody. This is the foundation of property. Hence,

OCCUPANT, in Law, is the person who first seizes, or gets possession of a thing. And,

OCCUPATION, in Law, is use or tenure, trade or mystery.

OCEAN, the *Sea*, that mighty element, which occupies more

than two-thirds of the terraqueous globe. In the Northern hemisphere, the land bears to the water the proportion of 419 to 1000; or nearly one half; but in the Southern hemisphere only of 129 to 1000; so that the whole mass of land is to that of sea, as 274 to 1000. And almost the whole of this vast body of water is collected in one immense basin called the Southern ocean.

Division of the waters into Oceans, Seas, Lakes, Straits, Gulfs, Bays or Creeks, Rivers, &c.—The waters are divided into three extensive oceans, (besides lesser seas, which are only branches of these,) viz. the Atlantic, the Pacific, and the Indian ocean. The Atlantic, or Western ocean, 3000 miles wide, divides the eastern and western continents. The Pacific, 10,000 miles over, divides America from Asia. The Indian ocean lies between the East Indies and Africa, being 3000 miles wide. The geographical definition of the ocean is a great and spacious collection of water, without any entire separation of its parts by land; as the Atlantic ocean. The sea is a smaller collection of water, which communicates with the ocean, confined by the land; as the Mediterranean and the Red sea. A lake is a large collection of water, entirely surrounded by land; as the lake of Geneva, and the lakes in Canada. A strait is a narrow part of the sea, restrained or lying between two shores, and opening a passage out of one sea into another; as the strait of Gibraltar, or that of Magellan. This is sometimes called a sound; as the strait into the Baltic. A gulf is a part of the sea running up into the land, and surrounded by it, except at the passage whereby it is communicated with the sea or ocean. If a gulf be very large, it is called an inland sea; as the Mediterranean: if it do not go far into the land, it is called a bay, as the Bay of Biscay; if it be very small, a creek, haven, station, or road for ships, as Milford Haven. Rivers, canals, brooks, &c. need no description: for these lesser divisions of water, like those of land, are to be met with in most countries, and every one has a clear idea of what is meant by them. But in order to strengthen the remembrance of the great parts of the land and water we have described, it may be proper to observe, that there is a strong analogy or resemblance between them.

On the Saltiness of the Sea.—Sea water is salt, while that of rivers is mild, fresh, sweet, and fit for human purposes. Some think that this saltiness arises from great beds of salt lying at the bottom of the sea. But others more rationally suppose it is owing to the following cause. Salt is one of the original principles of nature, and is mixed, in greater or less quantities, with most other bodies. Now all rivers run into the sea, and carry some salt with them; but no rivers run out of it, nor is any water taken from it, except by exhalation or evaporation. But chemists have demonstrably proved, that no salt can ascend in either of these ways; and consequently, all the salt carried into the sea by the immense numbers of rivers that run into it, remains behind, and occasions its saltiness. That no salt ascends from the sea, either by exhalation or evaporation, is evident from this, that rain-water, which falls from the clouds, and which was originally exhaled from the sea, is, of all kinds of water, the sweetest, purest, and lightest, and is made the standard by which philosophers judge of all other waters. The water of the ocean contains about the 30th part of its weight of salt: the water of the Baltic holds only from the 200th to the 100th part, consequently the water of the Baltic ought to stand 1-40th part higher from the bottom of the sea, than the water of the ocean, in order to maintain its hydrostatic equilibrium. It is observed on the Baltic shores, that the water subsides, and that its surface is lower in all parts than it formerly was. May not this be in consequence of the Baltic becoming saltier, and thus approximating to the specific gravity and height of the ocean? See TIDES.

The Currents of the ocean come next to be considered. Currents are certain progressive movements of the sea, by which all bodies floating therein are compelled to alter their course or velocity, or both, and submit to the laws imposed upon them by the current. The setting of a current is that point of the compass towards which the waters run, and the drift of the current is the rate it runs at in an hour. Currents in the sea are either natural or general, as arising from the diurnal revolution of the earth on its axis; or accidental, and particularly caused by the waters being driven against promontories, or

into gulfs and straits, where, wanting room to spread, they are driven back, and thus disturb the ordinary flux of the sea.

The following observations are made by Varenus:—"Currents are various, and directed towards different parts of the ocean, of which some are constant and others periodical. The most extraordinary current of the sea, is that by which part of the Atlantic or African ocean moves about by Guinea, from Cape Verd, towards the curvature or bay of Africa, which they call Fernando Po, viz. from west to east, contrary to the general motion. And such is the force of this current, that when ships approach too near the shore, it carries them violently towards the bay, and deceives the mariners in their reckoning. There is a great variety of shifting currents, which do not last, but return at certain periods; and these do, most of them, depend upon and follow the anniversary winds or monsoons, which by blowing in one place may cause a current in another. At Java, in the straits of Sunda, when the monsoons blow from the west, viz. in the month of May, the currents set to the eastward, contrary to the general motion. Also between the island of Celebes and Madura, when the western monsoons set in, viz. in December, January, and February, where the winds blow from the north-west, or between the north and west, the currents set to the south-east, or between the south and east. At Ceylon, from the middle of March to October, the currents set to the southward, and in the other parts of the year to the northward: because at this time the southern monsoons blow, and at the other the northern. Between Cochinchina and Malacca, when the western monsoons blow, viz. from April to August, the currents set eastward against the general motion, but the rest of the year set westward; the monsoon conspiring with the general motion. They run so strongly in those seas, that inexperienced sailors mistake them for waves that beat upon the rocks, known by the name of breakers. So for some months after the 15th of February, the currents set from the Maldives towards India on the east, against the general motion of the sea. On the shore of China and Cambodia, in the months of October, November, and December, the currents set to the north-west, and from January to the south-west, when they run with such a rapidity of motion about the shoals of Parcel, as to seem swifter than an arrow. At Pulo Condore, upon the coast of Cambodia, though the monsoons are shifting, yet the currents set strongly towards the east, even when they blow to a contrary point. Along the coasts of the bay of Bengal as far as the Cape Romania, at the extreme point of Malacca, the current runs southward in November and December. When the monsoons blow from China to Malacca, the sea runs swiftly from Pulo Cambi to Pulo Condore, on the coast of Cambodia. In the bay of Sans Bras, not far from the Cape of Good Hope, there is a current particularly remarkable, where the sea runs from east to west to the landward; and this more vehemently, as it becomes opposed by the winds from a contrary direction. The cause is undoubtedly owing to some adjacent shore, which is higher than this."

These currents constantly follow the winds, and set to the same point with the monsoon or trade-wind at sea. Under the equator, where the motion of the earth is the greatest, the currents are so violent, that they carry vessels very speedily from Africa to America; but absolutely prevent their return the same way; so that the ships are forced to run as far as the fortieth degree of latitude, to find a passage into Europe. The currents in the straits of Gibraltar almost constantly drive to the eastward, and carry ships into the Mediterranean: they are also usually found to drive the same way in St. George's Channel. The great violence and danger of the sea in the straits of Magellan, is attributed to two contrary currents setting in, one from the south and the other from the north sea.

Currents, as they relate to navigation, may be defined as certain progressive motions of the water of the sea in several places; by which a ship may happen to be carried forward more swiftly, or retarded in her course, according to the direction or setting of the current in with or against the course or way of the ship. The setting or progressive motion of the current, may be either quite down to the bottom, or to a certain determinate depth. As the knowledge of the direction and velocity of currents is a very material article in navigation, it

is highly necessary to discover both, in order to ascertain the ship's situation and course with as much accuracy as possible. This, some do by the ripples of the water, and by the driving of the froth along the shore, when in sight of it; but the most successful method which has been hitherto attempted by mariners, is the following:—A common iron pot, which may contain four or five gallons, is suspended by a small rope, fastened to its ears or handles, so as to hang directly upright, as when placed upon the fire. This rope, which may be from 70 to 100 fathoms in length, being prepared for the experiment, is coiled in the boat, which is hoisted out of the ship at a proper opportunity, when there is little or no wind to ruffle the surface of the sea. The pot being then thrown overboard into the water and immediately sinking, the line is slackened till about 70 or 80 fathoms run out, after which the line is fastened to the boat's stern, by which she is accordingly restrained, and rides as at anchor. The velocity of the current is then easily tried by the log and half-minute glass, the usual method of discovering the rate of a ship's sailing at sea. (See CALM.) The course of the stream is next obtained by means of the compass provided for this operation. This shews whether there be any current or no; and if any, which way it sets, and at what rate it drives: observing, however, to add something to the drift, for the boat's drift, for though she appear to stand still, yet, in reality, she is found to move. This addition experience has thus determined; if the line she rides by be 60 fathom, a third part of the drift is to be added, if 80 fathom a fourth, if 100 fathom a fifth.

If a ship sail along the direction of the current, it is evident the velocity of the current must be added to that of the vessel: if her course be directly against the current, it must be subtracted: if she sail athwart the current, her motion will be compounded with that of the current; and her velocity augmented or retarded according to the angle of her direction with that of the direction of the current: i. e. she will proceed in the diagonal of the two lines of direction, and will describe or pass through that diagonal in the same time wherein she would have described either of the sides by the separate forces. Hence it is plain, 1. If the velocity of the current be less than that of the ship, then the ship will advance so much as is the difference of these velocities. 2. If the velocity of the current be more than that of the ship, then will the ship fall as much astern as is the difference of these velocities. 3. If the velocity of the current be more than that of the ship, then will the ship remain stationary, the one velocity destroying the other. If the current thwarts the course of a ship, it not only diminishes or increases her velocity, but gives her a new direction, compounded of the course she steers, and the setting of the current.

Under-currents, are distinct from the upper or apparent, and in different places set or drive a contrary way. Dr. T. Smith makes it highly probable, that in the Downs, in the straits of Gibraltar, &c. there is an under-current, whereby as much water is carried out as is brought in by the upper current. This was confirmed by an experiment made in the Baltic sound, by the seamen on board one of the king's frigates: they went with the pinnace into the midstream, and were carried violently by the current. Soon after that, they sunk a basket with a large cannon bullet, to a certain depth of water, which gave check to the boat's motion; and sinking it still lower and lower, the boat was driven ahead to the windward, against the upper current, the current aloft not being above four or five fathom deep, and the lower the basket was let down, the stronger the under-current was found. Dr. Halley solves the currents setting in at the straits without overflowing the banks, by the great evaporation, without supposing any under-current. OCELOT, in Zoology, the Mexican cat, the *Felis Pardalis* of Linnæus.

OCHNA, a genus of plants belonging to the polyandria class, and in the natural order ranking with those whose order is doubtful.

OCHRA, in Ornithology, the name of a species of *moor-hen*.

OCHRA, a vegetable substance found in the West Indies, where it is used to thicken soup, as well as for other purposes.

OCHRE, (RED) REDDLE, or RED CHALK, is an iron ore of blood-red colour, which is sometimes found in powder, and

sometimes in a hardened state. It has an earthy texture, and stains the fingers when handled. The principal use of red chalk is for drawing; the coarser kinds are employed by carpenters and other mechanics, and the finer kinds by painters. For the latter purpose it should be free from grit, and not too hard. In order to free it from imperfections, and render it better for use, it is sometimes pounded, washed, mixed with gum, and cast into moulds of convenient shape and size. Under the name of reddle this substance is much used for the marking of sheep; and, when mixed with oil, for the painting of pales, gates, and the wood work of outbuildings.

OCHROMA, a genus of plants belonging to the monadelphia class, and ranking in the natural method under the 35th class, columbinæ.

OCTAGON, in Geometry, is a figure of eight sides and angles, which, when the sides and angles are all equal, is called a regular octagon, and when they are not both equal, an irregular octagon. The angle at the centre of an octagon is 45 degrees, and the angle of its sides 135 degrees. The area of a regular octagon whose side is $1 = 2(1 + \sqrt{2}) = 4.8284271$; and therefore when the side is s , the area $= 4.8284271 s^2$, and the radius of its circumscribing circle $=$

$$\frac{s}{\sqrt{(2 - \sqrt{2})}}$$

On a given Line A B to construct a regular Octagon.—On the extremities of the given line A B, erect the indefinite perpendiculars A F, B E, and produce A B both ways to m and n. Bisect the angles m A F, n B E, by the lines A H and B C, and take A H and B C both equal to A B. Draw G H and D C parallel to A F or B E, and each equal to A B; then from G and D as centres, with

radius A B, describe arcs cutting the perpendiculars in F and E. Join F G, F E, and E D, so is A B C D E F G H, the octagon required.

OCTANDRIA, the eighth class of Linnæus's sexual system, consisting of plants having eight stamina.

OCTANS HADLIENUS, *Hadley's Quadrant*, is the Polar constellation in the southern hemisphere; it contains forty-three stars, of which one is of the third magnitude, and all the rest are under the fourth. The splendid nebula near the South Pole, and called by sailors the Magellanic cloud, appears to the naked eye like a part of the Milky Way, but through a telescope like a mixture of clouds and stars.

OCTANT, the eighth part of a circle.

OCTANT, or *Octile*, is also an ancient term in astronomy, to denote one of the aspects, viz. when two planets are distant from each other 45°.

OCTAVE, in Music, an harmonical interval, consisting of seven degrees or lesser intervals.

OCTAVE. See CHORD.

OCTOBER, being the eighth month of the ancient Roman calendar, but the tenth according to the Julian year. This month contains 31 days, on or about the 22d of which the sun enters the sign Scorpio.

The *Kalendar of Animated Nature* around London, presents in this month, the red-wing, at the same time that snakes and vipers bury themselves. Hooded-crows and wood-pigeons arise, hen-chaldrins congregate and prepare to remove to another climate, leaving their males here. The snipe appears in the meadow ditches, wild geese quit the fens for the fye lands, rooks visit their nest trees, some larks sing, the woodcock returns, and spiders' webs abound.

In *Vegetable Nature*, we find the arbutus, the holly, the China holly-hock, and the China aster in bloom. The leaves of many trees are now quite yellow, and others fall off profusely. Various annual plants are in flower.

In the *Kitchen Garden*, culinary vegetables, as the small salads, lettuces, radishes, are sown, as are Mazagan beans, and hotspur or frame pease. To save seed, cabbages, savoy, beet, parsnips, carrots, turnips, bulbous and Welsh onions, are transplanted; newly raised annuals must be protected, culinary perennials propagated; endive and lettuce transplanted to warm borders. The routine culture of earthing,

hoeing, weeding, digging and trenching must not be neglected. Take up potatoes, beet, Jerusalem artichokes, parsnips, salsafy, scorzonera, skirret, and horse-radish of two years' growth, and preserve them in dry sand from the sea-shore. Gravel-pit sand is not by any means good for this purpose, as it very frequently holds the drift of vegetable substances, or earth.

In the *Hardy Fruit Department*, all sorts of hardy fruit trees are to be planted as soon as the leaves have dropped off; fig-trees are to be protected; late grapes shielded from frost by matting; except the raspberry, elder, and fig, all sorts of fruit trees are to be pruned; ground for new plantations is to be prepared; grapes, apples, and other fruits, must now be gathered; and long keepers are to be barrelled and stored in the fruit-room, or cellar.

In the *Culinary Hot-house Department*, in the glass-case without artificial heat, plant lettuces and cauliflowers under frames to stand the winter, sow small salads, slacken the heat in hot-beds and pits. In the pinery, shift and renew the bark-bed; prune in the forcing-house, cleanse and repair flues, mend broken glass, and paint when necessary.

In the *Flower Garden open Department*, sow annuals in pots for prolongation, in cold frames and pits; and some of the hardier sorts in warm borders, for the following early spring; as larkspur, adonis, belvedere, pansy, persicaria, annual stock. Propagate by dividing the root, as of daisies and of other edging plants. Plant border bulbs; transplant biennials and perennials, in the flower nursery, to stand till the spring. Protect auriculas, carnations, and other flowers, from heavy rains. Remove dahlia roots to dry in the open shed, preparatory to carrying them into the store-room. In the routine culture, prepare composts, stir the ground only in dry weather.

In the *Flower Garden Hot-house Department*, begin about the middle of the month to fill frames and pits with pots of mignonne, stocks, &c. for prolongation during the winter season; roses and hyacinths may now be put in bottom heat, and water-glasses brought into use. All plants must be replaced in the green-house, which should have air night and day when the temperature keeps up to 35°. Fires must be applied to the dry stove to keep the temperature at 47°; but in the bark or moist stove, the medium heat should be 70°.

In the *Pleasure Ground and Shrubbery*, plant hardy trees, prune evergreens, clear away all rubbish, roll, mow, sweep, hoe, weed. And in the *Nursery Department*, sow for stocks. The plum, cherry, almond, medlar, apple, pear, quince, barberry, service-tree, walnut, filbert, and hazel, may be sown. Cuttings of elder planted, fruit trees removed, as this is the best month for transplanting them. Permanent plantations and park scenery may now be planted, except in bleak situations, when the spring does best. Thin, prune, and sell generally; and let all drainings be worked now. In short, operations on grounds should now be executed vigorously, in all weathers; as it is better to keep the men on, than, with the view of saving a few pounds, lose a portion even of indifferent weather in October.

ODE, a song or a composition proper to be sung.

ODD NUMBER, that which cannot be divided into two equal integral parts, or which, when divided by 2, leaves a remainder 1.

ODDLY ODD NUMBER, that when divided by 4 leaves 3 for a remainder, or that which is of the form $4n + 3$.

ODOMETER, is an instrument for measuring the distance travelled over by a post chaise or other carriage; it is attached to the wheel, and shews, by means of an index and dial-plate, the distance gone over.

ODOURS, those invisible particles which disengage themselves from different bodies by the action of some gas, or by friction, mixture, and fermentation; and also by the exhalant vessels of animals and vegetables. They are also called effluvia, a learned term to conceal ignorance; for nobody can tell what these effluvia are. It is probable that these particles, if such there be, are kept in the state of gas, or vapour, by the presence of heat. All bodies, for any thing we know, may give out these particles, though we can perceive only such of them as affect our sense of smell.

What renders this probable, is, that many substances which are thought to be without smell in one circumstance, smell strongly in others. Flint and quartz, for instance, give out a

strong smell on being rubbed or struck: clay smells on being wetted; arsenic, on being heated, smells like garlic; and gold and other inodorous metals, in some circumstances, smell strongly. The particles must be very minute, however much they may affect the organ, at least if we may judge of this by their weight. This can be shewn by an experiment; but it takes some time to perform it.

Experiment on Odours. Take a grain of musk, very accurately weighed in the most delicate balance. Put it in such a place as it may be kept from moisture or dust, while it has free access to the air. Allow it to remain here for one, two, three, or twelve months. During all this time it will not cease to diffuse a strong odour all around it. Weigh it again very nicely at the end of the period you have allotted for the experiment, and you will find that it has not lost the least perceptible weight, though it has been for so long giving out daily and hourly a strong odour. Yet if we believe Le Cat, who has given us no reason for his opinion, but puts us off with a simile—odours are much heavier than air, and rise in it only in consequence of the velocity with which they are ejected from bodies, as a horse at full speed, and the wind together, raise a cloud of heavy dust; although however, the foregoing experiment has been repeatedly urged as conclusive, we are disposed to doubt the legitimacy of the inference. For why may not odours be similar in their nature to heat, to light, to the magnetic, to the galvanic, or to the electric principles?

Odours cannot be perceived by any of the senses but smelling. We cannot see them, hear them, nor touch them, and we think it is somewhat doubtful whether we can taste them. Do they not then bear a close analogy to light and heat in this respect; though they be not susceptible of reflection and refraction as light and heat are, because odours are not propagated in straight lines? They differ from sound in being capable of transmission through a vacuum made by an air pump, a property which might be advantageously made use of for investigating their properties more accurately than has yet been done.

During the rage for discovering chemical elements, which prevailed some years ago, it was maintained that *aroma* was an element of this sort, on the same vague fancy that colouring matter and extractive, and miasma, were set down as such; and the opinion still lingers among those who trust to the authority of names and of books, rather than be at the trouble of thought or inquiry for themselves. Fourcroy proved the opinion false as it regarded *aroma*; and we believe it is equally so in other cases.

How Smell is produced.—However this may be, it is clear enough, that the odoriferous principles, particles, or gases, are drawn up into the nostril in breathing; and by mixing or combining with the fluid which covers the nerves, produce in these nerves the sensation of smell. The moistness of the membrane is indispensable to the sensation of smell, for when the membrane becomes dry, no smell is perceived. The moisture may act, perhaps, as a solvent for the odoriferous principle; or it may increase the sensibility of the nerves. Smell also is only produced on drawing in the breath: when the air is returning from the lungs, it does not produce the sensation, unless the lungs, or the parts about the mouth, be diseased. In those persons who have the nose flattened, who have very small nostrils, or have the nose otherwise deformed or destroyed by accident or disease, this sense is either wholly wanting or very imperfect. When it is destroyed by palsy, or otherwise lost, the sense of touch still remains in it, as may be proved by introducing irritating substances. Odours are conveyed in a similar way through water to the organs of smell in fishes, as may be proved by a simple

Experiment.—Put a piece of half putrid flesh or fish, which smells strongly, into a box full of holes sufficient to admit of the passage of a large eel. Place this in a pond or other piece of water where eels abound; and in a few hours, it will be filled with eels, drawn thither by the smell of the meat. It is supposed by the French chemists, that the moisture of the nostrils has a stronger affinity, or appetency, as Darwin would call it, for odours than it has for air, and consequently, that it seizes on the odours, separates them from the air, and allows the air to pass on after parting with them. This is pure supposition.

Smell of Flowers in the Night.—The air, as all must have remarked, is better fitted when it is cool and moist, for conveying odours, than when dry and warm, as many flowers give out perfumes at night, which are not perceived by day; the nodding thistle (called by botanists *carduus nutans*) for example, the musk mallow, the sweet-scented orchis, and more particularly the night smelling wallflower, (called by botanists *cheiranthus tristis*.) In the case of the last of these, however, the greater moistness of the air at night will not explain the phenomenon, as the flower begins to smell about six o'clock, and in a few hours after becomes quite scentless, and remains so till the succeeding evening. Odours cannot well be classed, for animal odours, such as musk, are found in vegetables, as in the musk geranium; and vegetable odours are found in metals, as the smell of garlic from heated arsenic. The blossom of the stapelia smells so like putrid flesh, that it deceives the flesh-fly so far as to make her deposit her eggs in it; and the same takes place with some species of mushroom.

Effect of Odours on the Brain.—The nerves of smell, perhaps from their great exposure, and from their vicinity to the brain, are very apt when excited to act powerfully on the brain, and through it on the whole nervous system. Volatile alkali or hartshorn, as is well known, will in this way recover a person from fainting, or even prevent it; and pleasant odours, such as that of a bean-field, or of a flower garden, will sometimes induce headache. The smell of ardent spirits, of wine, and other fermented liquors, will in some cases produce intoxication, as if they had been taken into the stomach; and the smell of some medicines, Haller says, will act on the bowels like aperients taken by the mouth. M. Majendie is, as usual, doubtful of this explanation of the facts. He thinks in the case of the odour arising from wine, supposed to produce intoxication, that it is the actual particles of the wine floating into the air which are swallowed into the stomach; and that the same holds of a man having his bowels opened by pounding a large quantity of jalap or gamboge. This, however, will not explain the instantaneous emetic effect of some nauseous smells; nor perhaps the effect of strongly odoriferous medicines in hysteric affections.

Odours also act on the stomach through the influence of the associated nerves. We are told that Dumourier lived three days on the smell of hot bread; and Lord Bacon mentions the case of a man who lived a considerable time on the smell of garlic. Any very nauseous smell also will, in weak or sickly people, produce retching and squeamishness. It is probable that odours have likewise some influence on the lungs, though this is less easy to ascertain with accuracy. Some very pungent odours, however, excite coughing, such as the odour, if we may call it so, arising from oxymuriatic gas, from strong camphor, and from turpentine.

Use of Smell.—The use of the sense of smelling has certainly been much over-rated by some writers, in the instance of its guiding us to a choice of food. It acts no doubt so far in conjunction with taste, in determining what is fit to be eaten. Smell particularly warns us to avoid eating what is putrid. But man is in this much inferior to the lower animals, and has to trust both to his former experience, and to the reports of the taste, the eye, and the hand. In many cases we are even deceived by smell as to what is fit for food; as several things are not unwholesome which are by no means agreeable to the smell. We may give as instances of this, salt fish, onions, garlic, mustard, old cheese, which are offensive to the smell of most people, though they are generally relished as food. Besides, we are fond of many smells which are produced by substances otherwise quite useless to us; such as the fragrance of lavender, thyme, otto of roses;—in the same way as cats are fond of the smell of valerian and nepeta, though to them these are of no use whatever as food.

Experiment.—Take a piece of fresh valerian root, or the fresh stem of catmint (called by botanists *nepeta cataria*), and hold it out to a cat to smell. She will be as eager to seize it as if it were a mouse, though she will not eat it. By this means you may cause a cat to follow you to any distance you please. The experiment is not found to succeed with very young cats, either because they are deficient in smell while young, or because the influence of the odours depends on some sexual feeling.

Chemists long thought that the odoriferous part of bodies

formed a peculiar principle, distinct from all the other substances entering into their composition, and which they called *aroma*. Most bodies allow excessively minute particles to be detached and diffused in the atmosphere, which becomes loaded therewith, and sometimes carries them to a considerable distance, as well as conveys them to the olfactory organs. These particles constitute odours; and the infinite variety of them from different substances exhaled, renders it extremely difficult to classify them; but in a work of this description their classification is wholly unnecessary.

Bodies whose particles are fixed, are termed *inodorous*. The odour of every body is peculiar to itself, yet there is a great difference among them, as to the mode in which the odours are detached; with some it is only when they are heated, with others only when rubbed; some give only a very faint, others a very strong smell. Such is the tenuity of odorous particles, that a body may, during a long time, disengage them without sensible diminution of weight.

The atmosphere becomes loaded with the greater quantity, the warmer and the more moist it is. We know that in a flower garden, the air is never loaded with fragrant odours, nor is the smell ever the source of pleasing enjoyment, so much as in the morning, when the dew is evaporating by the rays of the sun. By the smell we perceive the odorous effluvia taken in by inspiration, and principally applied to the Schneiderian membrane, causing very delicate and delightful impressions; and no sensations are remembered in so lively a manner as those of peculiar odours.

Wonderful, indeed, is the variety of odours in the vegetable kingdom, and the sweet perfume of flowers is no less remarkable than the brilliancy of their lovely hues. Indeed, there is as much variety in the odours of flowers as in the flowers themselves. The extreme subtlety of the particles which flowers exhale, is such, that the smell of the rosemary which grows in Provence reaches twenty miles beyond sea; and a grain of amber can fill a room twenty feet square, and fifteen feet high, with its perfume.

Odorous bodies may be regarded as fugitive and tenacious; for the most pungent usually evaporate most speedily, as ether, alcohol, the spirituous tinctures, and essential volatile oils. They are likewise—*musky*, as those of musk and the rose, characterized by their tenacity;—*aromatic*, as the smell of the laurel;—*fragrant*, as the lily, saffron, and the jasmine, whose smell is very fugitive;—*fetid*, as of valerian and fungi;—*virulent*, as of poppies and opium; *spermiatic*, approaching that of garlic;—*pungent*, as of mustard;—*nauseous*, as of gourds, melons, cucumbers, and most cucurbitaceous plants;—*muratic*, as that of saline substances: distinguishable further, as *weak*, *strong*, *agreeable*, and *disagreeable*. In most cases, however, an odour is described by comparing it to that of some well-known substance.

Odours are supposed to possess nutritive, medicinal, and even poisonous properties; but, in the cases which have caused these opinions, probably the influence of odours has been confounded with the effects of absorption. A man after pounding jalap for some time, will be purged as if he had swallowed it. These effects ought not to be ascribed to the odour, but to the particles diffused in the atmosphere, and introduced into the circulation, either with the saliva, or the air which he inspired: to the same cause must be attributed the intoxication of persons exposed for some time to the vapour of spirituous liquors.

Liquids, vapours, and gases, with many solids, reduced to an impalpable or even coarser powder, have the power like odours of affecting the organs of smelling. But the mechanism of their action is rather different;—the air is the ordinary vehicle of odours, and transports them to a distance, as well as to the pituitary membrane which lines the nasal canals, but which is only affected by odours, however, when inhaled by the nostrils. Hence, when any odour is agreeable or grateful, we employ short and frequent inspirations, that the whole of the air received into the lungs may pass through the nasal fossæ; and, on the contrary, we breathe through the mouth, or suspend respiration, for a time, when the odour is disagreeable.

Bodies reduced to a coarse powder, have also a strong action on the pituitary membrane; their first action is painful; but custom at length converts the pain into a pleasure, as we see

in the example of tobacco. The odours in the upper part of the nasal cavities are more easily and strongly perceived; hence we modify inspiration so that the air may be directed towards this point, when we wish to smell a body strongly or accurately; hence also, snuff-takers endeavour to carry it towards the vault of the nostrils and olfactory nerves; the minute ramifications of which are distributed throughout the whole concavity of the former. Wonderful, indeed, is the care of nature in providing the nasal fossæ with a covering of hair to intercept the particles of odoriferous bodies from attacking the nerves too precipitately, and communicating impressions to the brain, till it is as it were previously prepared to be excited by them.

But, odours may be likewise propagated under an exhausted receiver; and certain bodies project odorous particles with some force. They may be attached to, or combined with, many liquids and solids, to fix or preserve them for any length of time.

OEUMENICAL, signifies the same with general, or universal, as oecumenical council, bishop, &c.

OEDEMA, in Surgery, a phlegmatic tumour, attended with paleness and cold, which obtains a place in any part of the body, but particularly the feet.

OENOTHERA, *Tree Primrose*, a genus of plants belonging to the octandria class, and in the natural method ranking under the 17th order Calycanchemæ.

OESOPHAGUS, the gula, or gullet, is a membranaceous canal, reaching from the fauces to the stomach, and conveying into it the food taken in at the mouth.

OESTRUS, *GAD FLY*, a genus of insects of the order diptera, extremely troublesome to horses, sheep, and cattle, depositing their eggs in different parts of the body, and producing very painful tumours, and sometimes death. The larvæ are without feet, short, thick, and annulate, and often furnished with small hooks. There are twelve species named, from the animals which they infest.

OFFENCE. Capital offences are those for which the offender loses his life; not capital where the offender, may lose his lands and goods, be fined, or suffer corporeal punishment, or both, but which are not subject to the loss of life.

OFFICE, that function, by virtue of which a person has some employment in the affairs of another. An office is a right to exercise any public or private employment, and to take the fees and emolument belonging to it, whether public, as those of magistrates; or private, as of bailiffs, receivers, &c. To offer money to procure the reversion of an office in the gift of the crown, is a misdemeanor at common law, and punishable by information; and even the attempt to induce, under the influence of a bribe, is criminal, though never carried into execution. An instance of which occurred under the administration of Mr. Addington, who prosecuted a tinman for offering him a sum of money for a place in the customs. Any contract to procure the nomination to an office, not within the statute of 6 Edward VI. is defective on the ground of public policy; and the money agreed to be given is not recoverable.

OFFICER. The great officers of the crown, or state, are the Lord High Steward, the Lord High Chancellor, the Lord High Treasurer, the Lord High President of the Council, the Lord Privy Seal, the Lord Chamberlain, the Lord High Constable, the Earl Marshal.

OFFICERS, *Field*, are such as command a whole regiment, as the colonel, lieutenant-colonel, and major.

OFFICERS, *General*, are those whose command extends to a body of forces, composed of several regiments: such are generals, lieutenant-generals, major-generals, and brigadiers.

OFFICERS, *Staff*, are such as, in the king's presence, bear a white staff, or wand; and at other times, on their going abroad, have it carried before them by a footman, bare-headed; such are the Lord Steward, Lord Chamberlain, Lord Treasurer, &c.

OFFICERS, *Commission*, are those appointed by the king's commission: such are all from the general to the cornet inclusive, who are thus denominated in contradistinction to warrant officers, who are appointed by the colonel's or captain's warrant, as quarter-masters, sergeants, corporals, and even chaplains and surgeons.

OFFICERS, *Subaltern*, are all who administer justice in the name of subjects; as those who act under the Earl Marshal,

Admiral, &c. In the army the subaltern officers are the lieutenants, cornets, ensigns, sergeants, and corporals.

OFFICIAL, by the ancient law, signifies him who is the minister of, or attendant upon, a magistrate. In the canon law, it is especially taken for him to whom any bishop generally commits the charge of his spiritual jurisdiction; and in this sense there is one in every diocese called *officialis principalis*, whom the laws and statutes of this kingdom call chancellor. 32 Hen. VIII. 15.

OFFICINA SCULPTORIS, the *Sculptor's Shop*, is a small constellation, composed by M: La Caille on the south of Cetus, and containing, according to Flamstead, twelve stars, spread over a considerable space of the firmament, but none of them exceeding the fifth magnitude.

OFFING, or **OFFIN**, that part of the sea a good distance from shore, where there is deep water, and no need of a pilot to conduct the ship.

OFFSETS, in Gardening, those young shoots that spring from the roots of trees or plants, which being carefully separated and planted in a proper soil, serve to propagate the species.

OFFSETS, in Surveying, are those short perpendiculars that are measured on the sides of irregular figures, for the more accurate determination of the area.

OFFSET Staff, a staff or rod used in surveying for measuring effects. It is commonly made of light wood ten links in length, divided and numbered from one end to the other.

OFFWARD, the situation of a ship which lies aground, and leans from the shore: thus they say, "the ship heels offward," when being aground she heels towards the water side; and "the ship lies with her stern to the offward, and the head to the shoreward," when her stern is towards the sea and head to the shore.

OGEE, in Architecture, or O, G, a moulding consisting of two members; one concave and the other convex, or of a round and hollow like an S.

OGIVE, in Architecture, an arch or branch of a gothic vault, which, instead of being circular, passes diagonally from one angle to another, and forms a cross with the other arches. The middle, when the ogives cross each other, is called the key, being cut in a rose or *cul de lamp*. The members or mouldings of the ogives are called *nerves*, *branches*, *veins*; and the arches which separate the ogives, *double arches*.

OIL, an unctuous inflammable substance, extracted from several natural bodies, whether animal or vegetable, as whale oil, olive oil, &c.

Oil obtained from Rape Seed by Pressure.—This is used in large quantities by clothiers and others, and likewise in medicine, and frequently for making the soap called green soap. It is also useful for various purposes in domestic life, and particularly for burning in lamps; but it is apt to become rancid, though there are means of purifying it. After the oil has been extracted, the refuse is called *oil-cake*, and is employed for the fattening of oxen, and in Norfolk is sometimes broken to pieces and strewed on the land as manure. The roots of rape plants may be eaten like turnips, but they have a stronger taste. The stalks of halm, if strong, may be advantageously employed for the enclosing fences of farm yards. They are, however, generally burnt, and in some parts of the country the ashes, which are equal to the best pot-ashes, are collected together and sold.

To Prepare an Oil for Clocks and other delicate Machinery.—The oil for diminishing friction in delicate machines, ought to be completely deprived of every kind of acid and mucilage: and to be capable of enduring a very intense degree of cold without freezing. In fact, it ought to consist entirely of elaine or the oily principle of solid fat, and to be perfectly free from stearine or solid fat. Now it is not a difficult matter to extract the elaine from all the fixed oils, and even from seeds, by the process recommended by Chevreul, which consists in treating the oil in a mattress with seven or eight times its weight of alcohol till boiling. The liquid is then to be decanted, and exposed to the cold, the stearine will then separate from it in the form of a crystallized precipitate. The alcoholic solution is afterwards to be evaporated to a fifth part of its volume, and the elaine will then be obtained, which ought to be colourless, insipid, without smell, and incapable of altering the colour of the infusion of litmus or turnsole, and having the consistence of pure white olive oil.

OIL MILL. This machine is used for expressing their oils from fruits, grains, &c.; and the following description, which is given in Dr. Gregory's *Mechanics*, is that of a Dutch mill employed for grinding and expressing lint and rape seed, &c. The original mill is put in motion, we believe, by wind; the Doctor, however, employs water as a first mover.

In the Plate **OIL MILL**, &c. fig. A, 1 is the elevation of a wheel, over or under shot, as the situation may require. 2, the bell-metal socket, supported by masonry, for receiving the outer gudgeon of the water wheel. 3, the water course.

Fig. B. 1, a spur wheel upon the same axis, having 52 teeth. 2, the trundle that is driven by No. 1, and has 78 staves. 3, The wallower, or axis for raising the pestles. It is furnished round its circumference with wipers for lifting the pestles, so that each may fall twice during one turn of the water wheel, that is, three wipers for each pestle. 4, a frame of timber, carrying a concave half-cylinder of bell metal, in which the wallower (cased in that part with iron plates) rests and turns round. 5, masonry supporting the inner gudgeon of the water wheel, and the abovementioned frame. 6, gudgeon of the wallower, which bears against a bell-metal step fixed in the wall. This double support of the wallower is found to be necessary in all mills which drive a number of heavy stampers.

Fig. C is the elevation of the pestle and press frame, their furnishings, the mortars, and the press pestles. 1, the six pestles. 2, cross pieces between the two rails of the frame, forming, with these rails, guides for the perpendicular motion of the pestles. 3, the two rails. The back one is not seen. They are checked and bolted into the standards No. 12. 4, the tails of the lifts, corresponding to the wipers upon the wallower. See the article **WIPER**. 5, another rail in front, for carrying the detents which hold up the pestles when not acting. It is marked 14 in fig. M. 6, a beam a little way behind the pestles. To this are fixed the pulleys for the ropes which lift and stop the pestles. It is represented by 16 in fig. M. 7, the said pulleys with their ropes. 8, the driver, which strikes the wedge that presses the oil. 9, the discharger, a stamper which strikes upon the inverted wedge, and loosens the press. 10, the lower rail with its cross pieces, forming the lower guides of the pestles. 11, a small cog wheel upon the wallower, for turning the spatula, which stirs about the oil seed in the chauffer pan. It has 28 teeth, and is marked No. 6 in fig. M. 12, the four standards, mortised below into the block, and above into the joists and beams of the building. 13, the six mortars hollowed out of the block itself, and in shape pretty much like a kitchen pot. 14, the feet of the pestles, rounded into cylinders, and shod with a great lump of iron. 15, a board behind the pestles, standing on its edge, but inclining a little backwards. There is such another in front, but not represented here. These form a sort of trough, which prevents the seed from being scattered about by the fall of the pestles, and last. 16, the first press box, (also hollowed out of the block,) in which the grain is squeezed, after it has come for the first time from below the millstones. 17, the second press box, at the other end of the block, for squeezing the grain after it has passed a second time under the pestles. 18, frame of timber for supporting the other end of the wallower, in the same manner as at No. 4, fig. B. 19, small cog wheel on the end of the wallower, for giving motion to the millstones. It has 28 teeth. 20, gudgeon of the wallower, bearing on a bell-metal socket fixed in the wall. 21, vessels for receiving the oil from the press boxes.

Fig. D. Elevation and mechanism of the millstones. 1, upright shaft, carrying the great cog wheel above, and the runner millstones below in their frame. 2, cog wheel of 76 cogs, driven by No. 19, of fig. C. 3, the frame of the runners. 4, the innermost runner, or the one nearest the shaft. 5, outermost ditto, being further from the shaft. 6, the inner rake, which collects the grain under the outer runner. 7, the outer rake, which collects the grain under the inner runner. In this manner the grain is always turned over and over, and crushed in every direction. The inner rake lays the grain in a slope, of which fig. O is a section; the runner flattens it, and the second rake lifts it again, as is marked in fig. P; so that every side of a grain is presented to the millstone, and the rest of the logger or nether millstone is so swept by them, that not a single grain

is left on any part of it. The outer rake is also furnished with a rag of cloth, which rubs against the border or hoop that surrounds the nether millstone, so as to drag out the few grains which might otherwise remain in the corner. 8, the ends of the iron axle which passes through the upright shaft, and through the two runners. Thus they have two motions: 1st, a rotation round their own axis; 2^{do}, that by which they are carried round upon the nether millstone on which they roll. The holes in these millstones are made a little wide; and the holes in the ears of the frame, which carry the ends of the iron axis, are made oval up and down. This great freedom of motion is necessary for the runner millstones, because frequently more or less of the grain is below them at a time, and they must therefore be at liberty to get over it without straining, and perhaps breaking, the shaft. 9, the ears of the frame which lead the two extremities of the iron axis. They are mortised into the under side of the bars of the square frame, that is carried round with the shaft. 10, The border or hoop which surrounds the nether millstone. 11 and 12, the nether millstone, and masonry which supports it.

Fig. K. Plan of the runner millstones, and the frame which carries them round. 1, 1, are the two millstones. 3, 3, 3, 3, the outside pieces of the frame. 4, 4, 4, 4, the cross bars of the frame which embrace the upright shaft 5, and give motion to the whole. 6, 6, the iron axis upon which the runners turn. 7, the outer rake. 8, the inner ditto.

Fig. L represents the nether millstone seen from above. 1, the wooden gutter, which surrounds the nether millstone. 2, The border or hoop, about six inches high all round, to prevent any seed from being scattered. 3, an opening or trap door in the gutter, which can be opened or shut at pleasure. When open, it allows the bruised grain collected in and shoved along the gutter by the rakes to pass through into troughs placed below to receive it. 4, portion of the circle described by the outer runner. 5, portion of the circle described by the inner one. By these we see that the two stones have different routes round the axis, and bruise more seed. 6, the outer rake. 7, the inner ditto. 8, the sweep, making part of the inner rake, occasionally let down for sweeping off all the seed when it has been sufficiently bruised. The pressure and action of these rakes is adjusted by means of wooden springs, which cannot be easily and distinctly represented by any figure. The oblique position of the rakes (the outer point going foremost) causes them to shove the grain inwards or toward the centre, and at the same time to turn it over, somewhat in the same manner as the mould board of a plough shoves the earth to the right hand, and partly turns it over. Some mills have but one sweeper, and, indeed, there is great variety in the form and construction of this part of the machinery.

Fig. M, profile of the pestle frame. 1, section of the horizontal shaft. 2, three wipers for lifting the pestles. See **WIPER**. 3, little wheel of 28 teeth, for giving motion to the spatula. 4, another wheel, which is driven by it, having 20 teeth. 5, horizontal axle of ditto. 6, another wheel on the same axle, having 13 teeth. 7, a wheel upon the upper end of the spindle, having 12 teeth. 8, two guides, in which the spindle turns freely, and so that it can be shifted higher and lower. 9, a lever, moveable round the piece No. 14, and having a hole in it at 9, through which the spindle passes, turning freely. The spindle has in this place a shoulder, which rests on the border of the hole 9; so that by the motion of this lever the spindle may be disengaged from the wheel work at pleasure. This motion is given to it by means of the lever 10, 10, moveable round its middle. The workman employed at the chauffer pulls at the rope 10, 11, and thus disengages the spindle and spatula. 11, a pestle seen sidewise. 12, the lift of ditto. 13, the upper rails, marked No. 3 in fig. C. 14, the rail, marked No. 5 in fig. C. To this are fixed the detents, which serve to stop and hold up the pestles. 15, a detent, which is moved by the rope at its outer end. 16, a bracket behind the pestle, having a pulley, through which passes the rope going to the detent 15. 17, the said pulley. 18, the rope at the workman's hand, passing through the pulley 17, and fixed to the end of the detent 15. This detent naturally hangs perpendicular by its own weight. When the workman wants to stop a pestle, he pulls at the rope 18, during the rise of the pestle. When

its greatest height, the detent is horizontal, and the pestle from falling by means of a pin projecting from the pestle, which rests upon the detent, the detent being held in that position by hitching the loop of the on a pin at the workman's hand. 19, the two lower marked No. 10, fig. C. 20, Great wooden, and sometimes lock, in which the mortars are formed, marked No. 21. 21, vessel placed below the press boxes for receiving 22, Chauffer, or little furnace, for warming the bruised 23, bucket in the front of the chauffer, tapering downward opening below in a narrow slit. The hair bags, in the grain is to be pressed after it has been warmed in the , are filled by placing them in this bucket. The grain out of the chauffer with a ladle, and put into these and a good quantity of oil runs from it through the slit bottom into a vessel set to receive it. 24, the spatula to the lower end of the spindle, and turning round the grain in the chauffer-pan, thus preventing it from to the bottom or sides, and getting too much heat. First part of the process at an oil-mill is bruising the der the runner stones.* That this may be more expedient, one of the runners is set about two-thirds of its kness nearer the shaft than the other. Thus they have treads; and the grain, which is a little heaped towards re, is thus bruised by both. The inner rake gathers it r the outer stone into a ridge, of which the section is stered in fig. O. The stone passes over it, and flattens it. thered up again into a ridge, of the form of fig. P. ie inner stone, by the outer rake, which consists of two The outer part presses close on the wooden border rrounds the nether stone, and shoves the seed obliquely , while the inner part of this rake gathers up what had ward the centre. The other rake has a joint near the of its length, by which the outer half of it can be raised ; nether stone, while the inner half continues pressing id thus scrapes off the moist paste. When the seed is tly bruised, the miller lets down the outer end of the his immediately gathers the whole paste, and shoves ely outwards to the wooden rim, where it is at last to a part that is left unboarded, and it falls through aghs placed to receive it. These troughs have holes ottom, through which the oil drips all the time of the n. This part of the oil is directed into a particular being considered as the purest of the whole; having tained, without pressure, by the mere breaking of the he seed.

ne mills this operation is expedited, and a much greater r of this best oil is obtained, by having the bed of , which supports the legger formed in a little furnace, tly heated. But the utmost care is necessary to pre- heat from becoming considerable. This, enabling the ssolve more of the fermentable substance of the seed, the oil to the risk of growing soon very rancid; and, al, it is thought a hazardous practice, and the oil does g so high a price.

the paste comes from under the stones, it is put into bags, and subjected to the first pressing. The oil ained is also esteemed as of the first quality, scarcely to the former, and is kept apart; (the great oil cistern ived into several portions by partitions.) The oil this pressing are taken out of the bags, broken to and put into the mortars for the first stamping. Here e is again broken down, and the parenchyma of the uced to a fine meal. Thus free egress is allowed to rom every vesicle in which it is contained; but it is dered much more clammy, by the forcible mixture of ilage, and even of the finer parts of the meal. When tly pounded, the workman stops the pestle of a mor- at the top of its lift, and carries the contents of the o the first chauffer pan, where it is heated to about the

temperature of melting bees' wax, (this, we are told, is the test,) and all the while stirred about by the spatula. From thence it is again put into hair bags, in the manner already described; and the oil which drips from it during this operation is considered as the best of the second quality, and in some mills is kept apart. The paste is now subjected to the second pressing, and the oil is that of the second quality. All this operation of pounding and heating is performed by one workman, who has constant employment by taking the four mortars in succession. The putting into the bags, and conducting of the presses, gives equal employment to another workman.

In the mills of Picardy, Alsace, and most of Flanders, the operation ends here; and the produce from the chauffer is increased, by putting a spoonful or two of water into the pan among the paste. But the Dutch take more pains. They add no water to the paste of this their first stamping. They say that this greatly lowers the quality of the oil. The cakes which result from this pressing, and are there sold as food for cattle, are still fat and softish. The Dutch break them down, and subject them to the pestles for the second stamping. These reduce them to an impalpable paste, stiff like clay. It is lifted out, and put into the second chauffer pan; a few spoonfuls of water are added, and the whole kept for some time as hot as boiling water, and carefully stirred all the while. From thence it is lifted into the hair bags of the last press, subjected to the press; and a quantity of oil of the lowest quality is obtained, sufficient for giving a satisfactory profit to the miller. The cake is now perfectly dry and hard, like a piece of board, and is sold to the farmers. Nay, there are small mills in Holland which have no other employment than extracting oil from the cakes which they purchase from the French and Brabanters; a clear indication of the superiority of the Dutch practice.

The nicety with which that industrious people conduct all their business is remarkable in this manufacture. In their oil cistern, the parenchymous part, which unavoidably gets through, in some degree, in every operation, gradually subsides; and the liquor, in any division of the cistern, comes to consist of strata of different degrees of purity. The pumps, which lift it out of each division, are in pairs; one takes it up from the very bottom, and the other only from half depth. The last only is barreled up for the market, and the other goes into a deep and narrow cistern, where the dreg again subsides, and more pure oil of that quality is obtained. By such careful and judicious practices, the Dutch not only supply themselves with this important article, but annually send considerable quantities even into those provinces of France and Flanders, where they bought the seed from which it was extracted. When we reflect on the high price of labour in Holland, on the want of timber for machinery, on the expense of building in that country, and in the enormous expense of windmill machinery, both in the first direction and the subsequent wear and tear, it must be evident, that oil mills erected in England on water falls, and after the Dutch manner, cannot fail of being a great national advantage. The chatellanie or seigneurie of Lille, alone makes annually between 30,000 and 40,000 barrels, each containing about 28 gallons.

What is here delivered is only a sketch. Every person acquainted with machinery will understand the general movements and operations. But the intelligent mechanic well knows, that operations of this kind have many minute circumstances which cannot be described, and which, nevertheless, may have great influence on the whole.—*Dr. Gregory's Machines*, vol. 2.

OIL GAS. If oil, tallow, or wax, be let fall upon red-hot iron, or made to pass through red-hot iron pipes, it will be resolved into a combustible gas. The fact was long known to chemists; and after the success of lighting by coal-gas was made apparent. Messrs. Taylor and Martineau contrived an ingenious apparatus for producing oil gas on a large scale, as a substitute for candles, lamps, and coal gas. Oil gas has several advantages over coal gas. It has no unpleasant smell in a room; it does not require the expense of being purified by lime: it will not injure in the least, books, pictures, or fine furniture; it has no corrosive effects on the pipes which convey it. It is far more economical than argand lamps, or mould or

are told, that in a mill at Reichenhoffen, in Alsace, a considerable ent has been made by passing the seed between two small iron fore it is put under the millstones. A great deal of work is said by this preliminary operation, and finer oil produced; which we probable. The stamping and pressing go on as in other mills.

wax candles. It gives a very bright light; and one cubic foot of oil gas will yield much more light than the same quantity of coal gas. This last is a great advantage, where saving of room is important.

OLBERS, a name sometimes given to the planet Pallas, discovered by Dr. Olbers, March 28th, 1802; but since the discovery of a second planet by the same astronomer, viz. Vesta, March 29th, 1807, the name Olbers is usually changed for that of Pallas, to prevent confusion between the two. See **PALLAS**.

OLEA, OLIVE, a genus of the diandria monogynia class and order. Natural order of sepiariæ. Jasmineæ, Jussieu. Essential character: corolla four-cleft; with subovate segments; drupe one-seeded. There are seven species. The olive seldom becomes a large tree; two or three stems frequently rise from the same root, from twenty to thirty feet in height, putting out branches almost their whole length, covered with a grayish bark. See **OLIVE** below.

OLEFIANT GAS. This gas differs from the common gas in this, that it consists of one prime of carbon and one of hydrogen, instead of one prime of carbon and two of hydrogen.

OLEIC ACID, is an oil obtained from potass and hogs' lard saponified, which has the property of saturating bases, and forming neutral compounds.

OLERON LAWS, laws relating to maritime affairs, and so called, because made when king Richard I. was at the Isle of Oleron, in Aquitaine.

OLFACTORY NERVES, the first pair of the head, so called from their being the immediate instruments of smelling.

OLIBANUM. A gum resin, the product of the *Juniperus Lycia*, brought from Turkey and the East Indies usually in drops or tears. The best is of a yellowish white colour, solid, hard, and brittle: when chewed for a little time, it renders the spittle white, and impresses an unpleasant bitterish taste; laid on burning coals, it yields an agreeable smell.

OLIGARCHY, a form of government wherein the administration of affairs is lodged in the hands of a few persons.

OLIVE. The olive in all ages has been held in peculiar estimation, as the bounteous gift of Heaven; it is still considered as emblematic of peace and plenty; the great quantity of oil which it produces in some countries, effectually realizes the latter of these blessings. Unripe olives pickled, especially the Provence and Lucca sorts, are to many persons extremely grateful; they are supposed to promote digestion.

OLIVINE, in Mineralogy, a species of the chrysolite family, found in the form of crystals, chiefly in basalt; colour between asparagus and olive green; specific gravity 3.2.

OLLARIS LAPIS, or **POTSTONE**, found abundantly near the lake of Como, is made into pots, and is also employed in Greenland. Its constituents are silica 39, magnesia 16, oxide of iron 10, carbonic acid 20, water 10. It occurs in beds of primitive slate.

OLYMPIAD, in Chronology, a period of four years, by which the Greeks reckoned their time; being thus called from the Olympic games held every fourth year, during five days near the summer solstice, on the banks of the river Alpheus, near Olympia, a city of Elis. The first Olympiad began the year 3938 of the Julian period, corresponding to 776 years before Christ. The computation by these games ended with the 404th, being the 440th of the present Christian era.

OMBROMETER, a name given by Mr. Pickering to the pluviometer, or rain gauge.

OMNIUM, a term in familiar use among stock-brokers and speculators in the funds, to express the whole of the articles which the subscribers to a loan receive from government. Thus, if the subscribers, according to their agreement with government, are to have for every hundred pounds advanced a certain sum in 3 per cent. consols, a further sum in 4 per cents, and a proportion of the long annuities, the blank receipts which they receive for making the instalments on the several articles, are, when disposed of, independent of each other, as the 3 per cent. consols only, called scrip; when the receipts are sold together as originally received, they are usually called omnium. As the omnium of every loan is the subject of extensive speculations, it generally is liable to considerable variations with respect to its current price, sometimes selling at a high premium, at other

times at a discount, according to the circumstances which take place between the agreement for the loan and the day fixed for paying the last instalment.

OMPHACITE, a mineral of a leek green colour, found in Carinthia.

OMPHALOPTER, a name sometimes given to a convex lens.

ONION, *The Common*, known by its cylindrical hollow leaves, and swelling pipy stalk, is a bulb that does not throw out offsets. Onions are propagated by seeds which are sown in spring; and the bulbs or roots arrive at perfection in the autumn. The whole plant when young is eaten as salad. Onions generally cease to grow towards the middle of August, the stalks and leaves at that time shrinking and turning brown. Shortly after this they must be drawn out of the earth; the tops and blades must be cut off; and the roots dried, either in a warm place, or by exposure to the sun. Spanish onions are of large size, and flattened shape; and Portugal onions are large, handsome bulbs, of roundish form. The kinds of onions in cultivation are, the Deptford, the Reading, the white Spanish, the Portugal, the Globe, and the Silver-skinned. All these varieties are usually sown in the spring of the year, and are good either eaten in their young state, or after they are dried in the winter. The silver-skinned kind is mostly in use for pickling. The globe and Deptford kinds are remarkable for keeping late in the spring. A portion of all the other sorts should be sown, as they are all very good, and some kinds will keep when others will not. By the common people, onions are frequently eaten raw with their food. This has particularly been the case, and from time immemorial, with the inhabitants of Egypt. By stimulating the stomach they are supposed to favour digestion; and some persons have imagined that they possess a large portion of alimentary matter: while others say that they afford little or no nourishment, and that, when eaten freely, they produce flatulencies, occasion thirst, headaches, and turbulent dreams. They have so much acrimony as generally to affect the breath for many hours; but when boiled or roasted this is in great measure dissipated, and they then exhibit some sweetness, with a considerable portion of mucilaginous matter. Onions are of great use in several culinary preparations, but particularly in soup and pickles. They are employed in medicine chiefly as poultices for swellings; and have been recommended, by some persons, to be rubbed on bald parts of the head, to promote the growth of the hair.

ONOCLEA, a genus of plants belonging to the cryptogamia class and order of Filices.

ONONIS, a genus of plants belonging to the diadelphia class.

ONOPERDUM, a genus of plants belonging to the syngenesia class, and in the natural method ranking under the 49th order, Compositæ.

ONOSMA, a genus of plants belonging to the pentandria class, and in the natural method ranking under the 41st order, Asperifoliæ.

ONYX. A chalcedony with alternate layers of white, black, and dark brown.

OPACITY, that quality of bodies which renders them opaque, in contradistinction to transparency.

OPAKE, or **OPAQUE**, not translucent nor transparent; or, that which prevents the free admission of the rays of light.

OPAL, in Mineralogy, a species of the quartz family, found in many parts of Europe, especially in Hungary. When first dug out of the earth it is soft, but it hardens and diminishes in bulk by exposure to the air. The specific gravity varies from 1.9. to 2.5. There are four sub-species, viz. the precious, the common, the semi, and the wood opal.

OPERA, a dramatic composition set to music, and sung on the stage, accompanied with musical instruments, and enriched with magnificent dresses, machines, and other decorations.

OPERA GLASS, in Optics, so called from its use in theatres, &c. it is sometimes called a "diagonal perspective," from its construction. It consists of a tube about four inches long, in each side of which there is a hole exactly against the middle of a plane mirror, which reflects the rays falling upon it to the convex glass, through which they are refracted to the concave eye-glass, whence they emerge parallel to the eye at the hole in the tube. This instrument is not intended to magnify objects

more than about two or three times. The peculiar artifice is to view a person at a small distance, so that no one shall know who is observed; for the instrument points to a different object from that which is viewed; and as there is a hole on each side, it is impossible to know on which hand the object is situated which you are looking at.

OPHTHALMIA, in Medicine, an inflammation of the membranes which invest the eye.

OPHIDIUM, a genus of fishes in the order Apodes.

OPHIOGLOSSUM, *Adder's Tongue*, a genus of plants belonging to the cryptogamia class, and to the order Filices.

OPHIORHIZA, a genus of plants belonging to the pentandria class, and in the natural method ranking under the 47th order, Stellatæ.

OPHIOXYLON, a genus of plants belonging to the polygamia class, and in the natural method ranking with those of which the order is doubtful.

OPHIRA, a genus of plants in the octandria class.

OPHIUCHUS, or **SERPENTARIUS**, and **SERPENS**, one of the old constellations, and which was anciently called *Æsculapius*. Its title of *Serpentarius* is due to the skill of Apollo's son in having restored Hippolytus to life, the Serpent entwined around Ophiuchus being the symbol of medicine, and of the gods who presided over this art; but the reptile may also be the symbol of prudence and vigilance.

The Boundaries and Contents.—This constellation, occupying a large portion of the heavens south of Hercules, is usually divided into two parts, one being assigned to Ophiuchus, and the other to Serpens. On the east it is bounded by Taurus Poniatowski and Scutum, south by Scorpio, and west by Boötes. The head of the Serpent is easily distinguished by some stars of the third and fourth magnitudes, which are found directly midway under Corona Borealis. They form, with γ and β of Hercules, the figure of a Y, the tail of which goes towards the south. Another of these, known as α , of the second magnitude, shines very brightly, and forms the heart of the Serpent. The other stars become mixed with those in Ophiuchus. There are 134 stars in this constellation, of which two are of the second, fourteen of the third, thirteen of the fourth magnitude, &c. The most brilliant among them is α *Ras Alhague*, having $261^{\circ} 38' 32''$ right ascension, and $12^{\circ} 42' 6''$ of north declination. This star appears E.N.E. $\frac{1}{4}$ E. point of the compass, at London, and it rises and culminates as follows: Meridian Altitude, $51^{\circ} 11' 6''$ N.

OPHRYS, *Twyblade*, a genus of plants belonging to the gynandria class, and in the natural method ranking under the 7th order, Orchidæ.

OPHRYS APIFERA, that is to say, *Bee Ophrys*, ranks among the few plants that are more generally admired than all the Orchidæ for their singular beauty and uncommon structure. The one in question so very much resembles the humble-bee in appearance, that I have known persons mistake this flower for the animal. It is unfortunate for the amateurs of gardening, that most plants of this tribe are difficult of propagation, and are not of easy culture. Botanists sometimes succeed with this and other species by the following method:—To take up the roots from their native places of growth as early as they can be found, and then to procure some chalk and sift it through a fine sieve, and also some good tenacious loam; mix both in equal quantities in water; a large garden-pot should then be filled with some rubble of chalk, about one-third deep, and then the above compost over it, placing the roots in the centre, at the usual depth they grew before. As the water drains away, the loam and chalk will become fixed closely round the bulbs, and they will remain alive and grow. By this method I have cultivated these plants for some years together. In this way all those kinds growing in chalk may be made to grow; but such as the *Orchis morio*, *maculata*, and *pyramidalis*,

may be grown in loam alone, planted in pots in the common way. Care should be taken that the pots in which they are planted are protected from wet and frost in the winter season.

OPIUM, obtained from poppy seeds, is procured from Turkey, and is also now produced to a large amount in India, and is exported to China. It is a powerful narcotic.

OPIUM, in Chemistry and Medicine, an inspissated gummy juice, which is obtained from the head of the "*papavera somniferum*." It is imported from Persia, Arabia, and other warm parts of Asia, in flat cakes covered with leaves to prevent their sticking together. It has a reddish brown colour, and strong peculiar smell; its taste at first is nauseous and bitter, but this soon becomes acrid, and produces a slight warmth in the mouth.

OPOBALSUM. The most precious of the balsams is that commonly called Balm of Gilead, Opobalsamum, Balsamæleon, Balsamum verum album, *Ægyptiacum*, *Judaicum*, *Syriacum* e Mecca, &c. This is the produce of the *amyris opobalsamum*, L. The true balsam is of a pale yellowish colour, clear and transparent, about the consistence of Venice turpentine, of a strong, penetrating, agreeable, aromatic smell, and a slightly bitterish pungent taste.

OPODELDOC. A solution of soap and alcohol, with the addition of camphor and volatile oils. It is used externally against rheumatic pains, sprains, bruises, and other like complaints.

OPOPONAX. A concrete gummy resinous juice, obtained from the roots of an umbelliferous plant, the *pastinaca opoponax*, which grows spontaneously in the warmer countries, and bears the cold of this.

OPPIATION, in Medicine, the act of obstructing or stopping up the ducts or passages of the body by redundant or peccant humours.

OPPOSITION, in Astronomy, is that aspect of any two heavenly bodies, when they are diametrically opposite each other, or 180° , that is, a semicircle, apart.

OPTICS, the science of vision, including Catoptrics and Dioptrics, and even Perspective; as also the whole doctrine of light and colours, and all the phenomena of visible objects. See PERSPECTIVE.

By a ray of light, is meant the motion of a single particle; and its motion is represented by a straight line. Any parcel of rays proceeding from a point, is called a pencil of rays. By a medium, is meant any pellucid or transparent body, which suffers light to pass through it. Thus, water, air, and glass, are called media. Parallel rays, are such as move always at the same distance from each other. If rays continually recede from each other, they are said to diverge. If they continually approach towards each other, they are said to converge. The point at which converging rays meet is called the focus. The point towards which they tend, but which they are prevented from coming to by some obstacle, is called the imaginary focus. When rays, after passing through one medium, on entering another medium of different density, are bent out of their former course, and made to change their direction, they are said to be refracted. When they strike against a surface, and are sent back again from the surface, they are said to be reflected. A lens, is glass ground into such a form as to collect or disperse the rays of light which pass through it. These are of different shapes, and from thence receive different names. A plano convex is one side flat, and the other convex. A plano concave is flat on one side, and concave on the other. A double convex, is convex on both sides. A double concave, is concave on both sides. A meniscus, is convex on one side and concave on the other. A line passing through the centre of a lens, is called its axis.

Of Refraction.—If the rays of light, after passing through a medium, enter another of a different density perpendicular to its surface, they proceed through this medium in the same direction as before. But if they enter obliquely to the surface of a medium, either denser or rarer than what they moved in before, they are made to change their direction in passing through that medium. If the medium which they enter be denser, they move through it in a direction nearer to the perpendicular drawn to its surface. On the contrary, when light passes out of a denser into a rarer medium, it moves in a direction farther

from the perpendicular. This refraction is greater or less, that is, the rays are more or less bent or turned aside from their course, as the second medium through which they pass is more or less dense than the first.

Upon a smooth board, about the centre *C*, (plate *Optics*, fig. 4.) describe a circle *H O K P*; draw two diameters of the circle, *O P*, *H K*, perpendicular to each other; draw *A D M* perpendicular to *O P*; cut off *D T* and *C I* equal to three-fourths *D A*; through *T I*, draw *T I S*, cutting the circumference in *S*; *N S* drawn from *S* perpendicularly upon *O P*, will be equal to *D T*, or three-fourths of *D A*. Then if pins be stuck perpendicularly at *A*, *C*, and *S*, and the board be dipped in the water as far as the line *H K*, the pin at *S* will appear in the same line with the pins at *A* and *C*. This shews, that the ray which comes from the pin *S* is so refracted at *C*, as to come to the eye along the line *C A*; whence the sine of incidence *A D* is to the sine of refraction *N S*, as 4 to 3. If other pins were fixed along *C S*, they would all appear in *A C* produced; which shews, that the ray is bent at the surface only. The same may be shewn at different inclinations of the incident ray, by means of a moveable rod turning upon the centre *C*, which always keeps the ratio of the sines *A D*, *N S*, as 4 to 3. Also the sun's shadow, coinciding with *A C*, may be shewn to be refracted in the same manner. The image *L* of a small object *S*, placed under water, is one-fourth nearer the surface than the object. And hence, the bottom of a pond, river, &c. is one-third deeper than it appears to a spectator.

To prove the refraction of light in a different way, take an upright empty vessel into a dark room; make a small hole in the window shutter, so that a beam of light may fall at the bottom at *a*, fig. 5, where you may make a mark. Then fill the basin with water, without moving it out of its place, and you will see that the ray, instead of falling upon *a* will fall upon *b*. If a piece of looking-glass be laid in the bottom of the vessel, the light will be reflected from it, and will be observed to suffer the same refraction as in coming in; only in a contrary direction. If the water be made a little muddy, by putting into it a few drops of milk, and if the room be filled with dust, the rays will be rendered much more visible.

Of Reflection.—When a ray of light falls upon any body, it is reflected so that the angle of incidence is equal to the angle of reflection; and this is the fundamental fact upon which all the properties of mirrors depend. Let a ray of light, passing through a small hole into a dark room, be reflected from a plane mirror, at equal distances from the point of reflection, the incident and the reflected ray will be at the same height from the surface. The same is found to hold in all cases when the rays are reflected at a curved surface, whether it be convex or concave.

The rays which proceed from any remote terrestrial object are nearly parallel at the mirror: not strictly so, but come diverging to it in several pencils, or, as it were, bundles of rays, from each point of the side of the object next the mirror, therefore they will not be converged to a point at the distance of half the radius of the mirror's concavity from its reflecting surface, but in separate points at a greater distance from the mirror. And the nearer the object is to the mirror, the further these points will be from it, and an inverted image of the object will be formed in them, which will seem to hang pendent in the air; and will be seen by an eye placed beyond it (with regard to the mirror,) in all respects like the object, and as distinct as the object itself.

If a man place himself directly before a large concave mirror, but further from it than its centre of concavity, he will see an inverted image of himself in the air, between him and the mirror, of a less size than himself. And if he hold out his hand toward the mirror, the hand of the image will come out towards his hand, and coincide with it, of an equal bulk, when his hand is in the centre of concavity, and he will imagine he may shake hands with his image. If he reach his hand further, the hand of the image will pass by his hand, and come between it and his body; and if he move his hand toward either side, the hand of the image will move towards the other: so that whatever way the object moves, the image will move the contrary way. A bystander will see nothing of the image, because none of the reflected rays that form it enter his eyes.

The images formed by convex specula are in positions similar to those of their objects; and those also formed by concave specula, when the object is between the surface and the principal focus; in these cases the image is only imaginary, as the reflected rays never come to the foci from whence they seem to diverge. In all other cases of reflection from concave specula, the images are in positions contrary to those of their objects, and these images are real, for the rays after reflection do come to their respective foci.

Colours.—The origin of colours is owing to the composition which takes place in the rays of light, each heterogeneous ray consisting of innumerable rays of different colours; this is evident from the separation that ensues in the well-known experiment of the prism. A ray being let into a darkened room, through a small round aperture, and falling on a triangular glass prism, is, by the refraction of the prism, considerably dilated, and will exhibit on the opposite wall an oblong image, called a spectrum, variously coloured, the extremities of which are bounded by semi-circles, and the sides are rectilinear. The colours are commonly divided into seven, which, however, have various shades gradually intermixing at their juncture. Their order, beginning from the side of the refracting angle of the prism, is red, orange, yellow, green, blue, purple, violet. The obvious conclusion from this experiment is, that the several component parts of solar light have different degrees of refrangibility, and that each subsequent ray in the order above mentioned is more refrangible than the preceding. As a circular image would be depicted by the solar ray unrefracted by the prism, so each ray that suffers no dilatation by the prism would mark out a circular image. Hence it appears that the spectrum is composed of innumerable circles of different colours. The mixture, therefore, is proportionable to the number of circles mixed together, but all such circles are mixed together, whose centres lie between those of two contingent circles, consequently the mixture is proportionable to the interval of those centres, i. e. to the breadth of the spectrum. If, therefore, the breadth can be diminished, retaining the length of the rectilinear sides, the mixture will be lessened proportionably, and this is done by the following process.

At a considerable distance from the hole *x*, place a double convex lens, fig. 6, whose focal length is equal to half that distance, and place the prism *z*, behind the lens; at a distance behind the lens, equal to the distance of the lens from the hole, will be formed a spectrum, the length of whose rectilinear sides is the same as before, but its breadth much less; for the undiminished breadth was equal to a line subtending, at the distance of the spectrum from the hole, an angle equal to the apparent diameter of the sun, together with a line equal to the diameter of the hole; but the reduced breadth is equal to the diameter of the hole only; the image of the hole formed by the lens at the distance of double its focal length, is equal to the hole; therefore, its several images in the different kinds of rays are equal to the same, i. e. the breadth of the reduced spectrum is equal to the diameter of the hole.

A prism placed in an horizontal position would project the ray into an oblong form; apply another horizontal prism similar to the former, to receive the refracted light emerging from the first, and having its refracted angle turned the contrary way from that of the former. The light, after passing through both prisms, will assume a circular form, as if it had not been at all refracted. If the light emerging from the first prism be received by a second, whose axis is perpendicular to that of the former, it will be refracted by this transverse prism into a position inclined to the former, the red extremity being least and the violet most removed from its former position; but it will not be at all altered in breadth.

Close to the prism *A*, fig. 7, place a perforated board *a b*, and let the refracted light, having passed through the small hole, be received on a second board *c d*, parallel to the first, and perforated in like manner; behind that hole in the second board place a prism, with its refracting angle downward; turn the first prism slowly about its axis, and the light will move up and down the second board; let the colours be transmitted successively, and mark the places of the different coloured rays on the wall after their refraction by the second prism, the red will appear lowest, the violet highest, the rest in the intermediate

Harris's improved Helmholtz Microscope

Double or Compound Microscope

Solar Microscope

in order. Here then the light being very much simplified, incidences of all the rays on the second prism exactly so; the red was least refracted, the violet most, &c. Permanency of these original colours appears from hence, they suffer no manner of change by any number of refractions is evident from the last mentioned experiment; nor reflection, for if any coloured body be placed in simple homogeneous light, it will always appear of the same colour in which it is placed, whether that differ from the colour of the body or not; e.g. if ultramarine and vermilion be in red light, both will appear red; in a green light, in a blue light, blue, &c. It is however to be allowed, nobody appears brighter when in a light of its own colour than another; and from this we see that the colours of nature arise from an aptitude in them to reflect some rays more copiously and strongly than others; but lest this phenomenon should produce a doubt of the constancy of the primary, it is proper to assign the reason of it, which is this; when placed in its own coloured light, the body reflects more of the predominant colour more strongly than any of the other mixed with it; therefore the proportion of the rays of predominant colour to those of the others, in the reflected light, will be greater than in the incident light; but when placed in a light of a different colour from its own, for the same reason the contrary effect will follow, i.e. the proportion of the predominant colour to the others would be less in the reflected than in the incident light, and therefore as its colour would be greater in the former case, and would be the latter, than if all the rays were effectually reflected, the colour of the predominant colour will be much greater in the former case than in the latter. White is compounded of primary colours mixed in their due proportions, for if a body be separated by the prism into its component, and at a certain distance a lens be so placed as to collect the dispersed coloured rays again into a focus, a paper placed perpendicularly to the rays in this point will exhibit whiteness. The same conclusion may be drawn from the experiment of mixing together paints of the same colour as the parts of the spectrum, and in the same proportion; the mixture will be as bright as a resplendent whiteness, because the co-mixed are less bright than the primary ones; this may be proved, by fixing pieces of cloth of all the seven principal colours on the rim of a wheel, and whirling it round at great velocity, it will appear to be white. Though seven principal colours are distinguishable in the prismatic spectrum, on examining the matter with more accuracy, we shall find there are, in fact, only three original colours, red, blue, and yellow; for the orange being situated between the red and the yellow, is only the mixture of these two; the green in like manner between the blue and yellow; and the violet from the red and blue. As the colour of a body therefore proceeds from a combination of the primary rays which it reflects; the action of rays flowing from any point of an object will, when connected by a glass, exhibit the same compound colour at the corresponding point of the image. Hence appears the reason why the images formed by glasses have the colours of the objects which they represent.

1.—Objects presented to the eye have their images formed on the back part of the retina, the rays of the incident light converging to their proper foci there by the refraction of the different humours; and for this office they are admirably adapted; for as the distance between the back and front of the eye is very small, and the rays of each of the pencils that form the image fall parallel, or else diverging on the eye, a strong refractive power is necessary for bringing them to their foci at the retina; but each of the humours, by its peculiar form and refractive power, contributes to cause a convergence of the rays; the cornea from its convex form; the crystalline by its double convexity and greater density than the aqueous; and the vitreous by its less density than the crystalline joined to its concave form. The structure of the eye is in general adapted to the action of parallel rays, but as the distances of visible objects are various, so the eye has powers of accommodating itself to the action of rays proceeding from different distances by altering the distance of the crystalline from the retina, which is done by the action of the ciliary ligaments.

Defective sight arises from an incapacity of altering the position of the crystalline within the usual limits. 1. When it cannot be brought close enough to the cornea, near objects appear indistinct; to this defect people in years are generally subject. 2. Where the crystalline cannot be drawn sufficiently near to the retina, remote objects appear indistinct; this is the defect under which short-sighted people labour. In each of these cases the images of the different points in the object would be diffused over small circles on the retina: and so being intermixed and confounded with each other, would there form a very confused picture of the object: for in the former case, fig. 8, the image of any point would be formed behind the retina, as the refraction of the eye is not sufficiently strong to bring the rays (diverging so much as they do in proceeding from a near point) to a focus at the retina. This defect will therefore be remedied by a convex glass *a b*, fig. 8, which makes the point whence the rays now proceed more distant than the object; therefore the rays falling on the eye will now diverge less than before, or else be parallel, and will of course be brought to a nearer focus, viz. at the retina.

In the latter case, the image is formed before the retina, fig. 9, because the refractive power of the eye is too great to permit rays so little diverging (as they do in proceeding from a distant point) to reach the retina before they are collected into a focus: in this case, the defect is supplied by a concave glass, which makes the point whence the rays diverge, nearer than the object; consequently, the rays falling on the eye will now diverge more than before, so as when refracted through the humours not to come to their focus before they reach the retina. Therefore spectacles are constructed concave for short-sighted, and convex for long-sighted people. And the frames of spectacles should be so bent, that the axes of both glasses may be directed to one point, at such a distance as you generally look with spectacles; by this means the eyes will fall perpendicularly upon both glasses, and make the object appear distinct; whereas if they fall obliquely upon the glasses the object will appear confused and indistinct.

Optical Instruments.—The impediments to the vision of very near objects arise from too great a divergence of the rays in each pencil incident on the eye, and are remedied by the microscope.

Microscopes.—The most powerful single microscopes are very small globules of glass, which any curious person may make for himself by melting the ends of fine threads of glass in the flame of a candle; or by taking a little fine powdered glass on the point of a very small needle, and melting it into a globule in that way. It was with such microscopes as these that *Lewenhoeek* made all his wonderful discoveries, most of which are deposited in the British Museum.

The Double or Compound Microscope differs from the preceding in this respect, that it consists of at least two lenses, by one of which an image is formed within the tube of the microscope; and this image is viewed through the eye-glass, instead of the object itself, as in the single microscope. In this respect the principle is analogous to that of the telescope, only that, as the latter is intended to view distant objects, the object-lens is of a long focus, and consequently of a moderate magnifying power, and the eye-glass of a short focus, which magnifies considerably the image made by the object lens. Whereas the microscope being intended only for minute objects, the object-lens is consequently of a short focus, and the eye-glass in this case is not of so high a magnifying power. We have explained this instrument under *Microscope*.

The Solar Microscope is a kind of camera obscura, which, in a darkened chamber, throws the image on a wall or screen. It consists of two lenses fixed opposite a hole in a board or window-shutter; one, which condenses the light of the sun upon the object, (which is placed between them,) and the other, which forms the image. There is also a plain reflector placed without, moved by a wheel and pinion, which may be so regulated as to throw the sun's rays upon the outer lens. *Mr. Adam's* most ingenious invention, the lucernal microscope, is also to be considered as a kind of camera obscura; only the light in this latter case proceeds from a lamp, instead of from the sun, which renders it convenient to be used at all times. But for a description of this elegant and most amusing

instrument, we must refer to his Microscopical Essay. See MICROSCOPE.

Telescopes.—From what has been said on the nature of the compound microscope, the principle of the telescope may be easily understood. Telescopes are, however, of two kinds; the one depending on the principle of refraction, and called the dioptric telescope; the other, on the principle of reflection, and therefore termed the reflecting telescope.

The parts essential to a dioptric telescope are, the two lenses A D and E Y, fig. 10. As in the compound microscope, A D is the object-glass, and E Y is the eye-glass; and these glasses are so combined in the tube, that the focus F of the one is exactly coincident with the focus of the other. Let O B then represent a very distant object, from every point of which pencils of rays will proceed, so little diverging to the object lens A D, that they may be considered as nearly parallel; I M will then be the image which would be formed on a screen by the action of the lens A D. For supposing O A and B D two pencils of rays proceeding from the extreme points of the object, they will unite in the focal point F, and intersect each other. But the point F is also the focus of the eye-glass E Y; and therefore the pencil of rays, instead of going on to diverge, will pass through it in nearly a parallel direction, so as to cause distinct vision. It is then plain, that as in the compound microscope, it is the image which is here contemplated; and this will account for the common sensation when people say the object is brought nearer by a telescope. For the rays, which after crossing proceed in a divergent state, fall upon the lens E Y, as if they proceeded from a real object situated at F. All that is effected by a telescope then, is to form such an image of a distinct object, by means of the object lens, and then to give the eye such assistance as is necessary for viewing that image as near as possible, so that the angle it shall subtend at the eye shall be very large compared with the angle which the object itself would subtend in the same situation. This is effected by means of the eye-glass, which refracts the pencils of rays, so that they may be brought to their several foci by the humours of the eye, as has been described. To explain clearly, however, the reason why it appears magnified, we must again have recourse to the figure. O B being at a great distance, the length of the telescope is inconsiderable with respect to it. Supposing, therefore, the eye viewed it from the centre of the object-glass C, it would see it under the angle O C B; let O C and B C then be produced to the focus of the glass, they will then limit the image I M formed in the focus. If then two parallel rays are supposed to proceed to the eye-glass E Y, they will be converged to its focus H; and the eye will see the image under the angle E H Y. The apparent magnitude of the object seen by the naked eye, is, therefore, to that of the image which is seen through the telescope, as the magnitude of the angle O C B, or I C M, to that of E H Y, or I G M. Now, the angle I G M is to I C M as C F to F G; that is, as the focal length of the object-glass to that of the eye-glass.—The magnifying power of these glasses may be augmented to a considerable degree, because the focal length of the object-glass, with respect to that of the eye-glass, may be greatly increased. This, however, would require a tube of immense length; because an eye-glass of a very short focus would cause such a dispersion of the rays of light, particularly towards the edges of the glass, that the view would be intercepted by the prismatic colours. Another manifest defect in these telescopes is, that the image appears inverted; this, however, is of no consequence with respect to the heavenly bodies; and on this account it is still used as an astronomical telescope. One of almost a similar construction is also used on board of ships as a night glass, to discover rocks in the ocean, or an enemy's fleet. Notwithstanding the inconvenience of exhibiting the objects inverted, more glasses than two cannot be employed from the paucity of light; and habit soon enables the persons who use them to discern objects with tolerable distinctness. The brightness of the appearance through any of these telescopes or microscopes, depends chiefly on the aperture of the object-glass. For if the whole of that glass was covered, except a small aperture in the middle, the magnitude of the image would not be altered; but fewer rays of every pencil being admitted, the object would appear ob-

scure. In a few words, the apparent distinctness or confusion of any object, viewed through glasses, depends on the mutual inclination of the rays in any one pencil to each other, when they fall on the eye; the apparent magnitude depends upon the inclination of the rays of different pencils to each other; the apparent situation depends upon the real situation of the extreme pencils; and the apparent brightness or obscurity depends on the quantity of rays in each pencil.

The well-known property in concave speculums, of causing the pencils of rays to converge to their foci, and there forming an image of any object that may be opposed to them, gave rise to the reflecting telescope. In this, the effect is precisely the same as that produced by the dioptric telescope; only that in the one case it is produced by reflected, and in the other by refracted light. Reflecting telescopes are made in various forms; and those principally in use in this country are distinguished by the names of their respective inventors, and are called the Newtonian, Gregorian, and Herschelien telescopes. The reflecting telescopes on the Gregorian principle, which is the most common, as it is found to be the most convenient, is constructed in the following manner:—At the bottom of the great tube, fig. 11, T T T, is placed a large concave mirror D U V F, whose principal focus is at *m*; and in the middle of this mirror is a round hole P, opposite to which is placed the small mirror L, concave toward the great one, and so fixed to a strong wire M, that it may be removed further from the great mirror, or nearer to it, by means of a long screw in the inside of the tube, keeping its axis still in the same line P *m* with that of the great one. Now, since in viewing a very remote object, we can scarcely see a point of it but what is, at least, as broad as the great mirror, we may consider the rays of each pencil, which flow from every point of the object, to be parallel to each other, and to cover the whole reflecting surface D U V F. But to avoid confusion in the figure, we shall only draw two rays of a pencil flowing from each extremity of the object into the great tube, and trace their progress through all their reflections and refractions to the eye *f*, at the end of the small tube *tt*, which is joined to the great one. Let us then suppose the object A B to be at such distance, that the rays C may flow from its upper extremity A, and the rays E from its lower extremity B; then the rays C falling parallel upon the great mirror at D, will be thence reflected, converging in the direction D G; and by crossing at I in the principal focus in the mirror, they will form the lower extremity of the inverted image I K, similar to the upper extremity A of the object A B; and passing on to the concave mirror L, (whose focus is at *a*.) they will fall upon it at *g*, and be thence reflected, converging in the direction *g* N, because *g m* is longer than *g a*; and passing through the hole P in the large mirror, they would meet somewhere about *r*, and form the upper extremity *a* of the erect image *a b*, similar to the upper extremity A of the object A B. But by passing through the plano-convex glass R, in their way, they form that extremity of the image at *a*. In the same manner the rays E, which come from the bottom of the object A B, and fall parallel upon the great mirror at F, are thence reflected, converging to its focus; where they form the upper extremity I of the inverted image I K, similar to the lower extremity B of the object A B; and thence passing on the small mirror L, and falling upon it at *h*, they are hence reflected in the converging state *h* O; and going on through the hole P of the great mirror, they would meet somewhere about *q*, and form there the lower extremity *b* of the erect image *a b*, similar to the lower extremity B of the object A B; but by passing through the convex glass R in their way, they meet and cross sooner, as at *b*, where the point of the erect image is formed. The like being understood of all those rays which flow from the intermediate points of the object between A and B, and enter the tube T T, all the intermediate points of the image between *a* and *b* will be formed; and the rays passing on from the image through the eye-glass S, and through a small hole *e* in the end of the lesser tube *tt*, they enter the eye *f*, which sees the image *a b* (by means of the eye-glass) under the large angle *c e d*, and magnified in length under that angle from *c* to *d*.

In the best reflecting telescopes the focus of the small mirror is never coincident with the focus *m* of the great one, where

the first image IK is formed, but a little beyond it, (with respect to the eye) as at n ; the consequence of which is, that the rays of the pencils will not be parallel after reflection from the small mirror, but converge so as to meet in points about g, e, r ; where they would form a larger upright image than $a b$, if the glass R was not in their way, and this image might be viewed by means of a single eye-glass properly placed between the image and the eye; but then the field of view would be less, and consequently not so pleasant; for that reason the glass R is still retained, to enlarge the scope or area of the field.

To find the magnifying power of this telescope, multiply the focal distance of the great mirror by the distance of the small mirror from the image next the eye, and multiply the focal distance of the small mirror by the focal distance of the eye-glass; then divide the product of the former multiplication by that of the latter, and the quotient will express the magnifying power. The difference between the Newtonian and Gregorian telescope is, that in the former the spectator looks in at the side through an aperture upon a plane mirror, by which the rays reflected from the concave mirror are reflected to the eye-glass; whereas, in the latter, the reader will see that he looks through the common eye-glass, which is in general more convenient.

The immensely powerful telescopes of Dr. Herschel are of a still different construction. This assiduous astronomer made several specula, which were of an immense magnifying power on distant objects. The object is reflected by a mirror, as in the Gregorian telescope, and the rays are intercepted by a lens at a proper distance, so that the observer has his back to the object, and looks through the lens at the mirror. The magnifying power will, in this case, be the same as in the Newtonian telescope; but there not being a second reflector, the brightness of the object viewed in the Herschelian is greater than that in the Newtonian or Gregorian telescope. In conclusion, Sir Isaac Newton's excellent maxim must not be omitted: "The art," says he, "of constructing good microscopes and telescopes, may be said to depend on the circumstance of making the last image as large and distinct and luminous as possible." See TELESCOPE.

Of the Rainbow, and other remarkable Optical Phenomena.—Since the rays of light are found to be decomposed by refracting surfaces, we can no longer be surprised at the changes produced in any object by the intervention of another. The vivid colours which gild the rising or the setting sun, must necessarily differ from those which adorn its noon-day splendour. There must be the greatest variety which the liveliest fancy can imagine. The clouds will assume the most fantastic forms, or will lower with the darkest hues, according to the different rays which are reflected to our eyes, or the quantity absorbed by the vapours in the air. The ignorant multitude will necessarily be alarmed by the sights in the heavens; by the appearance at one time of three, at another of five, suns; or circles of various magnitudes round the sun or moon; and thence conceive that some fatal change in the physical or the moral world, some fall of empires, or tremendous earthquake; while the optician contemplates them merely as the natural and beautiful effects produced by clouds or vapour, in various masses, upon the rays of light. One of the most beautiful and common of these appearances deserves particular investigation, as, when this subject is well understood, there will be little difficulty in accounting for others of a similar nature, dependent on the different refrangibility of the rays of light. Frequently, when our backs are turned to the sun, and there is a shower either around us, or at some distance before us, a bow is seen in the air, adorned with all or some of the seven primary colours. The appearance of this bow, which in poetical language is called the iris, and in common language the rainbow, was an inexplicable mystery to the ancients; and, though now well understood, continues to be the subject of admiration to the peasant and the philosopher.

We are indebted to Sir Isaac Newton for the explanation of this appearance; and by various easy experiments, we may convince any man that his theory is founded on truth. If a glass globe is suspended in the strong light of the sun, it will be found to reflect the different prismatic colours exactly in proportion to the position in which it is placed; in other

words, agreeably to the angle which it forms with the spectator's eye, and the incidence of the rays of light. The fact is, that innumerable pencils of light fall upon the surface of the globe, and each of these is separated as by a prism. To make this matter still clearer, let us suppose the circle BAW , fig. 12, to represent the globe, or a drop of rain, for each drop may be considered as a small globe of water. The red rays, it is well known, are least refrangible; they will therefore be refracted, agreeably to their angle of incidence, to a certain point A in the most distant part of the globe; the yellow, the green, the blue, and the purple rays, will each be refracted to another point. A part of the light, as refracted, will be transmitted, but a part will also be reflected; the red rays at the point A , and the others at certain other points, agreeably to their angle of refraction. It is very evident, that if the spectator's eye is placed in the direction of MW , or the course of the red-making rays, he will only distinguish the red colour; if in another situation, he will see only by the yellow rays; in another, by the blue, &c.; but, as in a shower of rain there are drops at all heights and all distances, all those that are in a certain position with respect to the spectator, will reflect the red rays, all those in the next station the orange, those in the next the green, &c. To avoid confusion, let us for the present imagine only three drops of rain, and three degrees of colours in the section of the bow, fig. 13. It is evident, that the angle CEP is less than the angle BEP , and that the angle AEP is the greatest of the three. This largest angle then is formed by the red rays, the middle one consists of the green, and the smallest is the purple. All the drops of rain, therefore, that happen to be in a certain position to the eye of a spectator, will reflect the red rays, and form a band or semicircle of red; those again in a certain position will present a band of green, &c. If he alters his station, the spectator will see a bow, though not the same bow as before; and if there are many spectators, they will each see a different bow, though it appears to be the same.

There are sometimes seen two bows, one formed as has been described, the other appearing externally to embrace the primary bow, and which is sometimes called the secondary or false bow, because it is fainter than the other, and what is most remarkable is, that in the false bow the order of the colours appears always reversed. In the true or primary bow we have seen that the rays of light arrive at the spectator's eye after two refractions and one reflection; in the secondary bow the rays are sent to our eyes after two refractions and two reflections, and the order of the colours is reversed, because in this latter case the light enters at the inferior part of the drop, and is transmitted through the superior. Thus, fig. 12, the ray of light which enters at B , is refracted to A , whence it is reflected to P , and again reflected to W , where, suffering another refraction, it is sent to the eye of the spectator. The colours of this outer bow are fainter than those of the other, because the drop being transparent, a part of the light is transmitted, and consequently lost at each reflection.

The phenomenon assumes a semicircular appearance, because it is only at certain angles that the refracted rays are visible to our eyes. The least refrangible, or red rays, make an angle of 42 degrees two minutes, and the most refrangible or violet rays an angle of 40 degrees 17 minutes. Now, if a line be drawn horizontally from the spectator's eye, it is evident, that angles formed with this line, of a certain dimension in every direction, will produce a circle; as will be evident, by only attaching a cord of a given length to a certain point, round which it may turn as round its axis, and in every point will describe an angle with the horizontal line of a certain and determinate extent. Let HO , for instance, fig. 14, represent the horizon, BW a drop of rain at any altitude, SB a line drawn from the sun to the drop, which will be parallel to a line SM drawn from the eye of the spectator to the sun. The course of part of the decomposed ray SB may be first by refraction from B to A , then by reflection from A to W ; lastly, by refraction from W to M . Now, all drops, which are in such a situation that the incident and emergent rays SB, MW , produced through them, make the same angle SNM , will be the means of exciting in the spectators the same idea of colour. Let MW turn upon HO as an axis, till W meets the horizon

brighter, and vanished the last of all. It is to be observed, that the order of the colours in the circles DEF, &c., was the same as in the common halos, namely, red next in; and the diameter of the inner circle was also about $\frac{1}{2}$ inch, which is the usual size of a halo. Parhelia have been for one, two, three, and four hours together; and in America they are said to continue some days, and to be from sun-rise to sun-set. When they disappear it sometimes rains, or snow falls in the form of oblong spiculæ.

Churchill, in Hudson's Bay, the rising of the sun is always deduced by two long streams of red light, which rise as the ice melts; and as they grow longer, begin to bend towards each other, till they meet directly over the sun, forming there a sort of parhelion or mock sun. These two streams of light to have their source in two other parhelia, which rise as the true sun; and in the winter season, when the sun rises above the haze or fog which is constantly found on the horizon, all these accompany him the whole day, and in the same manner as they rise. A fourth parhelion may sometimes be seen under the true sun; but this is uncommon. The cause of these is apparently the reflection of the sun's light and image from the thick and frozen clouds in the northern atmosphere, accompanied also with some degree of refraction. To enter upon a mathematical analysis of these phenomena would be only tedious, and very foreign to our purpose.

From what has been said upon this subject, it is evident that all the phenomena of colours depend upon two properties of light, the refrangibility and reflexivity of its rays.

The Inflection of Light.—The direction of the rays of light being, as we have seen, in their approach to certain bodies by reflection and refraction; and consequently we must suppose that there is some power in these bodies by which such rays are universally produced. If reflection was produced by the impinging of particles of light on hard or elastic bodies, or if they were in themselves elastic, the same effects would follow as in the impulse of other elastic bodies; but the direction of incidence could not be equal to the angle of reflection, the particles of light were perfectly elastic, or the bodies which they impinged were perfectly elastic. Now we know that the bodies on which these particles impinge are not perfectly elastic; and also that if the particles of light were perfectly elastic, the diffusion of light from the reflecting bodies would be very different from its present appearance: for as they can be perfectly polished, the particles of light, which are inconceivably small, would be reflected back by the intima on the surface in every direction; consequently we deduce from this conclusion, that the reflecting bodies are possessed of a power which acts at some little distance from their surfaces.

His reasoning is allowed to be just, it necessarily follows, that a ray of light, instead of impinging on a body, should be so near to it as to be within the sphere of that power which the body possesses, it must necessarily suffer a change of direction. Actual experiments confirm the truth of this; and to the change in the direction of a particle of light owing to its nearness to a body, we give the name of inflection.

In one of these experiments, made by Sir Isaac Newton, the nature of this subject will be easily understood. At the distance of two or three feet from the window of a darkened room in which was a hole three-fourths of an inch broad to admit the light, he placed a black sheet of pasteboard, having in the middle a hole about a quarter of an inch square, and directed the hole the blade of a sharp knife, to intercept a small portion of the light which would otherwise have passed through the window. The planes of the pasteboard and blade were parallel to each other; and when the pasteboard was removed at such a distance from the window, as that all the light coming into the room must pass through the hole in the pasteboard, he perceived what came through this hole on a piece of paper two or three feet beyond the knife, and perceived two streams of faint light shooting out both ways from the beam of light into the room. As the brightness of the direct rays obscured the refracted light, by making a hole in his paper he let them pass separately, and had thus an opportunity of attending closely to the two streams, which were nearly equal in length, breadth,

and quantity of light. That part which was nearest to the sun's direct light was pretty strong for the space of about a quarter of an inch, decreasing gradually till it became imperceptible; and at the edge of the knife it subtended an angle of about twelve, or, at most fourteen degrees. Another knife was then placed opposite to the former, and he observed, that when the distance of their edges was about the four-hundredth part of an inch, the stream divided in the middle, and left a shadow between the two parts, which was so dark, that all light passing between the knives seemed to be bent aside to one knife or the other; as the knives were brought nearer to each other, this shadow grew broader, till upon the contact of the knives the whole light disappeared.

Pursuing his observations upon this appearance, he perceived fringes, as they may be termed, of different coloured light, three made on one side by the edge of one knife, and three on the other side by the edge of the other: and thence concluded, that as in refraction the rays of light are differently acted upon, so are they at a distance from bodies by inflection; and by many other experiments of the same kind he supported his position, which is confirmed by all subsequent experiments. We may naturally conclude, that from this property of inflection some curious changes will be produced in the appearance of external objects. If we take a piece of wire of a less diameter than the pupil of the eye, and place it between the eye and a distant object, the latter will appear magnified, (fig. 16.) Let A be a church-steeple, B the eye, C the wire. The rays by which the steeple would have been otherwise seen are intercepted by the wire; and it is now seen by inflected rays, which make a greater angle than the direct rays, and consequently the steeple will be magnified.

Optical Wonder.—Mr. Scoresby's Journal of a Voyage to the Northern Whale Fishery, recently published, contains much information respecting the refractions which are usual in high latitudes: one very singular instance deserves to be noticed. "On my return to the ship, about eleven o'clock, the night was beautifully fine, and the air quite mild. The atmosphere, in consequence of its warmth, being in a highly refractive state, a great many curious appearances were presented by the land and ice-bergs. The most extraordinary effect of this state of the atmosphere, however, was the distinct inverted image of a ship in the clear sky, over the middle of the large bay or inlet before mentioned; the ship itself being entirely beyond the horizon. Appearances of this kind I have before noticed, but the peculiarities of this were—the perfection of the image, and the great distance of the vessel that it represented. It was so extremely well defined, that when examined with a telescope by Dolland, I could distinguish every sail, the general 'rig of the ship,' and its particular character: insomuch, that I confidently pronounced it to be my father's ship, the *Fame*, which it afterwards proved to be; though, on comparing notes with my father, I found that our relative position at the time, gave our distance from one another very nearly thirty miles beyond the horizon, and some leagues beyond the limit of direct vision. I was so struck by the peculiarity of the circumstance, that I mentioned it to the officer of the watch, stating my full conviction that the *Fame* was then cruising in the neighbouring inlet."

In nearly shutting the eyes and looking at a candle, there appear rays of light extending from it in various directions, like comets' tails; for the light, in passing through the eyelashes, is inflected; and consequently many separate beams will be formed, diverging from the luminous object. The power of bodies to inflect the rays of light passing near to them will produce different effects, according to the nature of the rays acted upon; consequently a separation will take place in the differently refrangible ray, and those fringes which were taken notice of by Sir Isaac Newton will appear in other objects, which are seen by the means of inflected rays. From considering thus the action of bodies upon light, we come to this general conclusion, for which we are indebted to our great philosopher—that light, as well as all other matter, is acted upon at a distance; and that reflection, refraction, and inflection, are owing to certain general laws in the particles of matter, which are equally necessary for the preservation of the beautiful harmony in the objects nearest to us, and to produce by their

joint action that great law by which the greater bodies in their system are retained in their respective orbits.

Table of Illuminating Power of Candles.—To ascertain the illuminating power of different sorts of candles, first weigh one of each sort to be tried; light them all at the same instant; and after the lapse of any given time, say half an hour, extinguish and again weigh them: compare how much each has lost in weight; that which has lost most, is the sort which affords the strongest light. In order farther to know the comparative expense of burning candles of different kinds, and of various sizes, the reader may consult the following table, which presents the average result of a series of experiments made with a view to the determination of this point:—

Description of wick.	Number of candles to the lb.	Weight of one candle.		Length of time one candle will burn.		Time that a pound will last.	Expense of burning candles of each description, at 10s. a suppository, price 10s. per doz. in farthings and fourth parts, where they can be reduced the proportional expense when they are at any other price.	
		oz.	dr.	h.	m.			h.
Small wick	18	4	3	5	50	23	6-078	
	18	3	2	40	50	33	9-173	
	16	15	2	40	44	—	10-909	
	12	5	3	27	41	32	11-857

	4	4	—	9	3	36	12	15-911
	3	5	2	17	30	51	4	16-634

Optic Inequality, in Astronomy, is an apparent irregularity in the motions of the planets and other celestial bodies, being thus called, because it does not arise from any real inequality of the moving body, but from the situation of the eye of the observer.

Optic Nerves, the second pair of nerves springing from the crura of the medulla oblongata, and passing thence to the eye.

Optic Place of a planet, is its place as seen by the eye.

Optic Pyramid, is a pyramid formed by the visual rays proceeding from the eye, and passing through the extremities of any picture, when these rays are continued to terminate in a plane perpendicular to the observer.

OPTION, the power or faculty of wishing or choosing, or the choice a person makes of any thing. Hence we say, when a new suffragan bishop is consecrated, the archbishop of the province, by a customary prerogative, claims the collation of the first vacant benefice or dignity in that see; this is the bishop's option.

OR, *Gold*, in Heraldry, denoted by small points all over the field, in engravings of arms; and it is supposed to signify of itself generosity, splendour, or solidity.

ORANGE. See CITRUS.

ORATORIO, a sort of sacred drama, in dialogue, recitative, duet, trios, ritornellos, and choruses; the subjects being usually taken from scripture, and the music being in the finest taste, and best chosen strains. Lent is the season for performances of this description.

ORBIS MAGNUS, the great orb in which the sun was supposed to revolve.

ORBIT, the path of any celestial body. The orbits of the several planets were, even after the restoration of the Pythagorean system of astronomy by Copernicus, supposed to be circular, having the sun in their common centre, which, indeed, was such a rational and simple hypothesis, that it is not at all singular both Copernicus and Kepler, as well as other astronomers of that day, were so unwilling to give up this idea. However, Kepler, after an immense number of observations upon the planet Mars, found that it was impossible to recon-

cile his observations with that theory, and he therefore abandoned it; but now, though he changed the figure from a circle to an ellipse, he still, by supposing the sun in the centre, found nearly the same difficulty in accounting for some of the observed phenomena. At length, however, it happily occurred to him to place the sun in one of the foci, with which position every observed irregularity perfectly agreed; and by that perseverance, for which he is so eminently distinguished, he came finally to those fundamental laws which still bear his name, viz.—1. The planets all revolve in elliptic orbits situated in planes passing through the centre of the sun, the latter body occupying one of the foci of the ellipse. 2. Equal areas are described in equal times. That is, if a line be supposed to join the central and revolving body, that line passes over or describes equal areas in equal times. 3. The squares of the times of revolution in planetary bodies, are as the cubes of their distances from the sun.

ORCHARD, a plantation of fruit trees. In planting an orchard great care should be taken that the soil is suitable to the trees planted in it; and that they are procured from a soil nearly of the same kind, or rather poorer than that laid out for an orchard. As to the situation, an easy rising ground, open to the south-east, is to be preferred. Miller recommends planting the trees fourscore feet asunder, but not in regular rows; and would have the ground between the trees ploughed, and sown with wheat and other crops, in the same manner as if it was clear from trees; by which means the trees will be more vigorous and healthy, will abide much longer, and produce better fruit. If the ground has been pasture, the green-sward should be ploughed in the spring before the trees are planted; and if it is suffered to lie a summer fallow, it will greatly mend it, provided it is stirred two or three times to rot the grass, and prevent the growing of weeds. At Michaelmas it should be ploughed pretty deep, in order to make it loose for the roots of the trees, which, if the soil is dry, should be planted in October; but if it is moist, the beginning of March will be a better season. If several sorts of fruit trees are to be planted on the same spot, you should observe to plant the largest growing trees backwards, and so proceed to those of less growth, continuing the same method quite through the whole plantation; by which means the sun and air will more easily pass through the whole orchard. When you have planted the trees, you should support them with stakes, to prevent their being blown out of the ground by the wind; and the following spring, if the season should prove dry, cut a quantity of green turf, and lay it about the roots, with the grass downwards; by which means a greater expense of watering will be saved, and after the first year they will be out of danger. Whenever you plough the ground betwixt these trees, you must be careful not to go too deep amongst their roots, which would greatly damage the tree; but if you do it cautiously, your stirring the face of the ground will be of great service to them; though you should observe never to sow too near the tree, nor to suffer any great rooting weeds to grow about them; because this would starve them, by exhausting the goodness of the soil, which every two or three years should be mended with dung or other manure. These trees, after they are planted out, will require no other pruning besides cutting off their bad branches, or such as cross each other.

ORDEAL, a form of trial for discovering innocence or guilt, formerly practised over almost all Europe, and which prevailed in England from the time of Edward the Confessor, till it was abolished by a declaration of Henry III. It was called *purgatio vulgaris*, or *judicium*, in opposition to *bellum*, or combat, the other form of purgation. In England, an offender, on being arraigned, and pleading not guilty, had it in his choice to put himself upon God and his country, that is, upon the verdict of the jury; or upon God alone, on which account it was called the judgment of God, it being presumed that God would deliver the innocent. The more popular kinds of ordeal were red-hot iron and water; the first for freemen and people of fashion, and the last for peasants. Fire ordeal was performed either by taking up in the hand a piece of red-hot iron, of one, two, or three pounds weight; or else by walking barefoot and blindfold over nine red-hot ploughshares, laid at unequal distances; and if the party escaped unhurt he was

adjudged innocent; if not, he was condemned as guilty. Water ordeal was performed either by plunging the bare arm up to the elbow in boiling water, and escaping unhurt thereby; or by casting the person suspected, into a river or pond of water: if he floated therein, without any action of swimming, it was deemed an evidence of his guilt; but if he sunk, he was acquitted. 4 Black. 340.

ORDER. See ARCHITECTURE.

ORDER OF A LINE, in the theory of Curves, denotes the dimension of the equation by which the line is expressed; it being of the 1st, 2d, 3d, &c. order, according as the equation is of the 1st, 2d, 3d, &c. degree or dimension.

ORDERS, or ORDINATION. No person shall be admitted to the holy order of deacon under 23 years of age; nor to the order of priest, unless he is 24 complete; and none shall be ordained without a title, that is, a nomination to some cure or benefice, and he shall have a testimonial of his good behaviour, for three years past, from three clergymen; and the bishop shall examine him, and, if he sees cause, may refuse him. And before he is ordained, he shall take the oath of allegiance and supremacy before the ordinary, and subscribe the thirty-nine articles.

ORDINARY, in common and canon law, is one who has an ordinary or immediate jurisdiction in ecclesiastical causes in such a place.

ORDINARY Seaman, implies one who can make himself useful on board, but is not an expert or skilful sailor; the latter being termed an *able seaman*. Able seamen have consequently more wages than the ordinary.

Ships in ORDINARY, are those which being laid up are under the direction of the master attendant.

ORDINATE, in the theory of Curves, any right line drawn from a point in the absciss to terminate in the curve; and if drawn perpendicularly to the absciss, it is called a *right ordinate*. It is a general property of the ordinates of a curve, that when perpendicular to the axis of a line of the second order, that is, in the circle and conic sections, the ordinates are all bisected by that axis, making the sum of all the ordinates on one side equal to that of those on the other; and in lines of the third order, where a line may cut the curve in three places, the ordinate on the one side is always equal to the sum of the ordinates on the other.

ORDNANCE, a general name for all sorts of great guns used in war.—See *Canon*, and *Plate Oil Mill*, &c.

ORDNANCE, Office of, an office kept within the Tower of London, which superintends and disposes of all the arms, instruments, and utensils of war, both by sea and land, in all magazines, garrisons, and forts in Great Britain.

ORES. Metals, when found in a state of combination with other substances, have the name of *ores*. They are in general deposited in veins of various thickness, and at various depths in the earth. The mode of obtaining them is to penetrate from the surface of the earth to the vein, and there to follow it, in whatever direction it may lie. The hollow places thus formed are called *mines*, and the men employed in them are denominated *miners*. When the veins are at a great depth, or extend to any considerable distance beneath the surface of the earth, it is necessary at intervals to make openings or *shafts* to the surface, for the admission and circulation of the air; and also to draw off the water which collects at the bottom, by means of drains, pumps, or steam-engines, as the situation or circumstances require. After the metallic ores are drawn from the mine, they in general go through several processes before they are in a state fit for use. Some of them are first washed in a running water, to clear them from earthy particles. They are then piled together with combustible substances, and burnt or roasted, for the purpose of ridding them of the sulphur or arsenic with which they may happen to be combined, and which rises from them in a state of fume or smoke. Thus having been freed from impurities, they undergo the operation of melting, in furnaces constructed according to the nature of the respective metals, or the uses to which they are to be subsequently applied. See **METALS**.

ORFFYREUS'S WHEEL, in Mechanics, is a machine so called from its inventor, which he imagined to be a perpetual motion. This machine consisted of a large circular wheel or

drum, twelve feet diameter, and fourteen inches in depth, and very light; it was formed of an assemblage of deals, the intervals between which were covered with waxed cloth, in order to conceal the interior parts of it. The two extremities of an iron axis, on which it turned, rested on two supports. On giving the wheel a slight impulse in either direction, its motion was gradually accelerated; so that after two or three revolutions, it required so great a velocity as to make twenty-five or twenty-six turns in a minute. This rapid motion it actually preserved during the space of two months, in the chamber of the landgrave of Hesse, the door of which was kept locked, and sealed with the landgrave's own seal. At the end of that time it was stopped, to prevent the wear of the materials. The professor, who had been an eye-witness to these circumstances, examined all the external parts of it, and was convinced that there could not be any communication between it and any neighbouring room. Orffyreus, however, was so incensed, that he broke the machine in pieces, and wrote on the wall, that it was the impertinent curiosity of professor Gravesande which made him take this step. The prince, who had seen the interior of this wheel, being asked whether, after it had been in motion some time, there was any change observable in it, and whether it contained any pieces that indicated fraud or deception, answered both questions in the negative, and declared, that the machine was of a very simple construction.

ORGAN, in general, an instrument or machine designed for the production of some certain action or operation; in which sense the mechanic powers, machines, and even the veins, arteries, nerves, muscles, and bones of the human body, may be called organs. The organs of sense are those parts of the body by which we receive the impressions or ideas of external objects, being commonly reckoned five, viz. the eye, ear, nose, palate, and cutis. See **MAMMALIA**, p. 613.

ORGAN, a wind instrument blown by bellows, and containing numerous pipes of various kinds and dimensions, and multifarious tones and powers. Of all musical instruments this is the most proper for the sacred purpose to which it is most generally applied, in all countries wherever it has been introduced. Its structure is lofty, elegant, and majestic; and its solemnity, grandeur, and rich volume of tone, have justly obtained it an acknowledged pre-eminence over every other instrument. The church organ consists of two parts; the main body, called the great organ, and the positive or little organ, which forms a buffet, commonly placed before the great organ. The size of an organ is generally expressed by the length of its largest pipe; thus they say, an organ of 8, 16, 32 feet, &c. The organ in the cathedral church at Ulm in Germany, is 93 feet high and 28 broad; its largest pipe is 13 inches diameter, and it has 16 pairs of bellows.

ORGANIC REMAINS. As it is fashionable to dignify various departments of knowledge and human speculation with Greek names, the researches of mankind respecting organic remains have received the pompous name *Oryctology*. Oryctology is then the science which teaches the natural history of those animal and vegetable substances which are dug out of the earth in a mineralized state. In the following slight sketch of the history of these substances it will be seen that the remarkable situations in which they have been found, and the extraordinary changes which they have undergone, have led to the adoption of various contradictory and absurd notions respecting their nature and origin; which have been corrected, as just ideas have been obtained respecting the formation of the earth itself. Xenophanes, more than 400 years before Christ, was led to the belief of the eternity of the universe, by discovering the remains of different marine animals imbedded in rocks and under the surface of the earth. Herodotus ascertained the existence of fossil shells in the mountains of Egypt, and was thereby induced to conclude that the sea must have once covered those parts. In the pyramids of Egypt, mentioned by this author, and which has been built at so early a period that no satisfactory accounts could be derived from tradition respecting their erection, the stones were found to contain the remains of marine animals, and particularly of such as exist no longer in a recent state, and differ essentially from all known animals. These were supposed by Strabo, who saw the fragments of

these stones lying around the pyramids, to be the petrified remains of the animals which had been used for food by the workmen. Brachet, M. de Ligny, and Strabo, have all agreed, and variously commented upon, the existence of animal remains thus wonderfully preserved. In the works of Pliny, many bones are mentioned, particularly the buccardina, resembling at first sight, but which was, doubtless, a cast formed in a shell, either a bryozoa, bearing the form of a tongue, and supposed to flutter like the moon when in its wane; ammonites, found in the coast of Sicily; horns of ammon, resembling those of the ram; bryozoa, lepidotes, like the scales of fishes; ammonites, bearing a resemblance to the seeds of poppy; bryozoa, in the form of a tortoise; sponges, supposed to be sea-weeds or fishes.

The fossil remains of quadrupeds, especially those of the larger kind, are more necessarily excited the attention and wonder of every curious inquirer into natural history. In various parts of the country have been found the remains of elephants, and of other animals of considerable magnitude. In Ireland have been found the remains of deer, of a size far exceeding any now known; and in Scotland have been found the remains of a stag, as well as those of an enormous animal of the ox kind, but larger than even the urus. In France, Germany, and Italy, and indeed in most parts of Europe, remains of large animals have been found; and in both North and South America the remains of enormous unknown animals have been discovered. According to Pallas, from the Tanais to the continental angle nearest to America, there is hardly a river in this immense space, especially in the plains, upon the shores or in the bed of which have not been found the bones of elephants and of other animals not of that climate. From the mountains by which Asia is bounded, to the frozen shores of the ocean, all Siberia is filled with prodigious bones; the best ivory (fossil) is found in the countries nearest to the arctic circle, as well as in the eastern countries, which are much colder than Europe under the same latitude; countries where only the surface of the ground becomes thawed during summer. The number of bones which have been discovered of the rhinoceros is very considerable, not only in Siberia, but in Germany, and in other parts of Europe; and in the opinion of St. Fond, founded not only on the discoveries of Pallas and others, but on his own observations made on the immense collection of Merck, joined with that of the landgrave of Hesse Darmstadt, are of the species with double horns. An entire body of an animal of this species, still possessing the skin, fat, and muscles, has been dug up near the river Willioni, in the eastern part of Siberia, from under a hill which is covered with ice the greatest part of the year. St. Fond states, in confirmation of the above opinion, that another head obtained by Pallas from Siberia, one existing in the cabinet of the elector of Mannheim, and another in the cabinet of Merck, are all apparently similar to the head of the double-horned rhinoceros of Africa.

Much remains to be ascertained with respect to the fossil remains of elephants, of which considerable numbers have been found in various parts of England, France, Germany, and Italy; but no where so abundantly as in Siberia. In America indeed the remains of enormous unknown species of this animal are also very abundant. There appears to be only two species of elephants now in existence: one (the Asiatic) being distinguished by its grinders being divided into transverse and nearly parallel plates, and the other (the African) having these plates disposed in lozenge-like forms. The elephantine remains which have been found in Siberia have been supposed to have belonged to no existing species; for though the teeth are formed of plates disposed parallel to each other, as in the Asiatic, these plates are said to be thinner, and consequently more numerous; but this distinction is by no means established. The remains of elephants discovered in this country, seem referable, in most instances, to the Asiatic. The remains of an animal of an enormous size has been found at Paraguay, at no great distance from the river Plata, which being properly arranged, has been formed into a skeleton, and placed in a cabinet of natural history at Madrid. This animal, twelve feet in length and six in height, is distinguished as well by its general form as by the largeness of its claws.

In various parts of Scotland, and of France, in Tuscany,

the Venetian, and in North America, have been found the fossil remains of some animal, which has been supposed to be a variety of the urus of Julius Caesar, or of the bison. To the fossil remains already mentioned, may be added the animal incognitum of Syme in Languedoc; the enormous stag found in the mosses of Ireland; the gigantic tapir, found at the bottom of the black mountains of Languedoc; the bears, of two species now unknown, found in Bareith; and the numerous animals, of unknown species, which the admirably indefatigable Cuvier is perpetually discovering, in that mine of fossils, the quarries of gypsum near Paris. Of the mineral remains of man, no well-attested instance is known. In a cavern, indeed, in Mendip Hills, some human bones have been found invested with stalactites. These appear to be but comparatively of modern existence. Scheuchzer published an essay describing a supposed skeleton of a man; which was undoubtedly the remains of some large fish.

ORGANICAL DESCRIPTION OF CURVES, the method of describing them on a plane by means of instruments, as the compasses and ruler, which are the most simple, and are the only instruments admitted into plane or elementary geometry; but other instruments have been invented for the description of various curves, as elliptic compasses, conchoid, ellipse, hyperbola, parabola, &c.

ORGANZINE, in Commerce, a description of silk usually imported from Italy into this country. It is of the utmost importance to the manufacturer, as none of the principal articles could be fabricated without it; and the Italians, aware of this, long kept the art of throwing it a most profound secret. It was introduced into this country by the enterprise and skill of Messrs. Thomas and John Lombe.

ORIBASIA, a genus of plants belonging to the pentandria class, and in the natural method ranking under the 37th order stellata.

ORIENT, the east or eastern point of the horizon.—*Orient Equinoctial*, that point of the horizon where the sun rises when in the equinoctial.—*Orient Estival*, is that point of the horizon where the sun rises in the middle of summer.—*Orient Hybernal*, that point of the horizon where the sun rises in the middle of winter.

ORIENTAL, any thing or place situated to the eastward of an observer.

ORIGANUM, **ORIGANY**, or *Marjorum*, a genus of plants belonging to the didynamia class, and in the natural method ranking under the 42d order.

ORIGINAL, in the courts of King's Bench, the usual original writ issued in the actions, as for action of trespass upon the case. This court does not issue originals in actions of debt, covenant, or account, &c. whereas the Court of Common Pleas proceeds by original in all kinds of actions; but to arrest and sue a party to outlawry, it is used in both cases.

ORILLON, in Fortification, is a small rounding of earth, faced with a wall, raised on the shoulder of those bastions that have casemates, to cover the cannon in the retired flank, and prevent their being dismounted by the enemy.

ORIOLES, **ORIOLE**, in Ornithology, a genus belonging to the order picæ. These birds are inhabitants of America, except in a few instances: they are a noisy and gregarious, frugivorous, granivorous, and voracious race, very numerous, and often have pensile nests. The several species, which are very numerous, since Latham describes no less than forty-five, seem to be principally distinguished by their colour.

ORION, the most brilliant constellation in the heavens, is highly embellished by several adjacent constellations of great splendour; and, when it comes to the meridian, there is then above the horizon the most splendid view of the celestial bodies that the starry firmament affords to the eye of the beholder; and this magnificent exhibition is visible to all the habitable world, because the equinoctial passes nearly through the middle of the constellation.—*Boundaries and Contents*: N. by Taurus; E. by Monoceros; S. by Lepus, and W. by Eridanus and Taurus. There are seventy-eight stars in this constellation, viz. two of the first magnitude, four of the second, four of the third, sixteen of the fourth, &c. Orion is a paratantillon of Taurus, and the brilliant Betelgeux, on his right shoulder, of the first magnitude, having 7° 21' 54" N. declination, and right

86° 21' 17", appears in the Eastern horizon at Longitude E. by N. point of the compass, and rises and sets the first day of every month in the year, as in the Table: Merid. Alt. 45° 50' 54".

RISES. ho. mi.	CULM. ho. mi.	MONTH.	RISES. ho. mi.	CULM. ho. mi.

River, another name for the constellation *Eri-*

or **ORLET**, in Architecture, a fillet under the ovolo round of a capital; when it is at the top or bottom it is called cincture.

O, a platform of planks laid over the beams in the ship of war, whereon the cables are usually coiled. It contains the sail-rooms, the purser's, surgeon's, boat and carpenter's cabins, and the several officers' store-rooms. The second and lowest decks are called Orlops.

HOGALUM LATIFOLIUM and **UMBELLATUM**, are al plants, and are often cultivated for their beautiful 'be' season for planting the bulbs is about the month of April.

HOGALLUM, *Star of Bethlehem*, a genus of plants to the hexandria class, and in the natural method under the 10th order, coronariæ.

HODOLOGY, that branch of Zoology which treats of the habits of birds.

BIRD. Linnæus, whose ornithology we have followed, ranges the whole class of birds under six orders, to the different figures of their beaks, viz. Accipitres, vultures, and hawks; upper mandible with an angulation. 2. Picæ, as crows, jackdaws, humming-birds, &c.; bill compressed, with feet formed for perching and climbing. 3. Anseres, as geese, ducks, gulls, and swans; bill with skin, broad at the tip, some with and some without. 4. Grallæ, as herons, woodcocks, and ostriches; billish, tongue fleshy; some with three, some with four. 5. Gallinæ, as peacocks, pheasants, turkeys, and combs; bill convex, upper mandible arched. 6. Passeres, as larks, and swallows; bills conic, and sharp-pointed. This order are comprehended pigeons.

HOPUS, a genus of plants belonging to the diadelphous class, and in the natural method ranking under the 32d pilionaceæ.

HORYNCHUS VEL PARADOXUS, the bird-quadruped of New South Wales, a singular quadruped, which has been properly classed in the Linnæan system. The most remarkable circumstance, in this curious animal, is the great size of its head with that of a duck; the under part of the bill having its margin indented, as in ducks; and the instrument for chewing being situated behind, within the throat.

SPRAXINUS, the ash which produces manna.

ANCHE, a genus of plants belonging to the didynamous class, and in the natural method ranking under the 40th rosaceæ.

BITTER VETCH, a genus of plants belonging to the didynamous class, and in the natural method ranking under the 40th pilionaceæ.

TIUM, a genus of plants belonging to the hexandria class, and in the natural method ranking under the 2d peritæ.

LAN. In the city of London there is a court of record for the care and government of orphans.

MENT, is a mineral substance, of lemon-yellow colour, and consists of arsenic in combination with about forty-three parts of sulphur, and is about thrice as heavy as water. It is found in a massive and crystallized state, in Natolia, Hungary, Turkey, and some other countries. In the latter, the crystals are so confused, that their figures can hardly be determined. The orpiment of commerce is an

artificial production, and is chiefly imported from different parts of the Levant. The Turks and other Orientals use it in the depilatories which serve to render bald the top of the head. A very beautiful but fugitive pigment, called *king's yellow*, is prepared from this mineral, and other preparations of orpiment are occasionally used by painters, and also by dyers and calico-printers. The whole of these, however, are extremely poisonous.

ORRERY, an astronomical instrument for exhibiting the motions of the heavenly bodies, was first constructed by Graham, but its name is derived from one made by Rowley for the Earl of Orrery, which was supposed by Sir R. Steel to be the first ever constructed; and he therefore gave it the above name in honour of the Earl, and attributes the invention to Mr. Rowley; whose name it has ever since retained, though the error on which it was adopted has long been corrected.

ORRIS-ROOT, is the root of a white-flowered kind of iris, called *Florentine Iris*, which is a native of Italy, and is distinguished by having two flowers on each stalk; the petals bearded, and the leaves sword-shaped. In a dried state, this root is well known on account of its grateful odour, which somewhat approaches that of the violet. It is consequently much used in the manufacture of hair powder, and other articles for which an agreeable scent is required. It is sometimes employed in medicine as a pectoral or expectorant, and sometimes in dropsies. In a recent state the root is extremely acrid; and, when chewed, excites in the mouth a pungent taste, which continues for several hours; but this acrimony is almost wholly dissipated by drying. Orris-root is chiefly imported into this country from Leghorn.

ORTHODROMICS, in Navigation, is the same as Great Circle Sailing, and indicates the straight or shortest distance, which can only be in the arc of a great circle.

ORTHOGRAPHIC PROJECTION OF THE SPHERE, is that projection which is made upon a plane passing through the middle of the sphere, by an eye placed vertically at an infinite distance.

ORTHOGRAPHY, that part of grammar which teaches the nature and affections of letters, and the just method of spelling or writing.

ORTHOGRAPHY, in Geometry, the art of drawing or delineating the fore-right plan of any object, and of expressing the heights or elevations of each part. It is called orthography, from its determining things by perpendicular lines falling on the geometrical plane.

ORTHOGRAPHY, in Architecture, the elevation of a building.

ORTHOGRAPHY. See PERSPECTIVE.

ORTIVE, or **EASTERN AMPLITUDE**, in Astronomy, is an arch of the horizon intercepted between the place where a star rises and the east point of the horizon.

ORTOLAN. See EMBERIZA.

ORYZA, **RICE**, a genus of the dyginia order, in the hexandria class of plants; and in the natural method ranking under the 4th order, graminæ. There is but one species, namely, the sativa or common rice. This plant is greatly cultivated in most of the Eastern countries, where it is the chief support of the inhabitants; and great quantities of it are brought into England and other European countries every year, where it is much esteemed for puddings, &c. it being too tender to be produced in these northern countries without the assistance of artificial heat: but from some seeds which were formerly sent to Carolina, there have been great quantities produced, and it is found to succeed there as well as in the Eastern countries. It has been cultivated with advantage in Lombardy in Italy; but the stagnant water in which it grows being injurious to health, the government does not permit the extension of the cultivation to new lands.

OSCILLATION, in Mechanics, vibration, or the reciprocal ascent and descent of a pendulum.

Axis of OSCILLATION, is a right line passing through the point of suspension parallel to the horizon.

Centre of OSCILLATION, is that point in a vibrating body into which, if all the matter of the body were collected, the vibrations would be performed in the same time.

OSCULATION in the theory of Curves, denotes the contact between any curve and its osculatory circle; or that circle which has the same curvature as the curve at the given point of

osculation. If AC be the evolute of the involute curve AEF , and the tangent CE be the radius of curvature at the point E , with which and the centre C , if the circle BEG be described, this circle is said to osculate or kiss the curve AEF , in the point E ; which point E is called the point of osculation; CE the osculatory radius, or radius of curvature; the circle BEG the osculatory circle; and the evolute AC the locus of all the centres of the osculatory circles.

Point of osculation is also used to denote the concurrence of two branches of a curve that touch each other; which differs from a cusp or point of retrocession, in this, that in the latter case, although it forms a point of concurrence, the curve terminates there; whereas in a point of osculation, the curve does not terminate, but is continued on both sides. Thus, in the annexed figure, A is a point of retrocession, and B a point of osculation.

OSCULATORY CIRCLE, or **KISSING CIRCLE**, is the same as the circle of curvature; such is the circle BEG in the preceding figure, article **OSCULATION**.

OSIER, a very valuable shrub, of the *salix viminalis*, used principally in basket-making.

OSMIUM. A new metal lately discovered by Mr. Tenant among platina, and thus called by him from the pungent and peculiar smell of its oxide. Pure metal, previously heated, did not appear to be acted upon by acids. Heated in a silver cup with caustic alkali, it combined with it, and gave a yellow solution similar to that from which it was procured. From this solution acids separate the oxide of osmium.

OSMUNDA, *Moonwort*, a genus of plants belonging to the cryptogamia class.

OSTIFICATION. The deposition of the phosphate and carbonate of lime on the soft solids of animal bodies, as, on the lungs, liver, heart, &c.

OSTENSIVE DEMONSTRATION, is a direct geometrical demonstration, in contradistinction to an apogogical one, or that which depends upon a *reductio ad absurdum*.

OSTRACTION, *Trunk-fish*, a genus of fishes, of the order nantes; the generic character is, teeth pointing forwards, cylindric, rather blunt; body mailed by a bony covering.

OSTREA, the *Oyster*, in Zoology, a genus belonging to the order of *vermes testacea*. There are thirty-one species, principally distinguished by peculiarities in their shells. The common oyster is reckoned an excellent food, and is eaten both raw and variously prepared. The oyster differs from the muscle in being utterly unable to change its situation. It is entirely without a tongue, which answers the purposes of an arm in the other animal, but nevertheless is often attached very firmly to any object it happens to approach. Oysters usually cast their spawn in May, which at first appears like drops of candle-grease, and sticks to any hard substance it falls upon. These are covered with a shell in two or three days; and in three years the animal is large enough to be brought to market. As they invariably remain in the places where they are laid, and as they grow without any other seeming food than the afflux of sea-water, it is the custom at Colchester, and other parts of England, where the tide settles in marshes on land, to pick up great quantities of small oysters along the shore, which, when first gathered, seldom exceed the size of sixpence. These are deposited in beds where the tide comes in, and in two or three years grow to a tolerable size. They are said to be better tasted for being thus sheltered from the agitations of the deep; and a mixture of fresh water entering into these repositories, is said to improve their flavour and increase their growth and fatness. The oysters, however, which are prepared in this manner, are by no means so large as those found sticking to rocks at the bottom of the sea, usually called rock-oysters. These are sometimes found as broad as a plate, and are

admired by some as excellent food. But what is the size of these compared to the oysters of the East Indies, some of whose shells have been seen two feet over? The oysters found along the coast of Coromandel, are capable of furnishing a plentiful meal for eight or ten men; but it seems universally agreed that they are no way comparable to ours for delicacy of flavour.

OTACOUS TIC, a name sometimes given to a hearing trumpet and other instruments for improving the sense of hearing.

OTIS, the *Bustard*, in Natural History, a genus of birds of the order gallina. Gmelin mentions eleven species, and Latham nine. We shall notice only the following:—The great bustard, found in the plains of Europe, Asia, and Africa, but has never been observed in the New Continent. In England it is occasionally met with on Salisbury Plain, and in the wolds of Yorkshire, and formerly was not uncommonly seen in flocks of forty or fifty. It is the largest of British land birds, weighing often twenty-five or thirty pounds. It runs with great rapidity, so as to escape the pursuit of common dogs, but falls speedily a victim to the greyhound, which often overtakes it before it has power to commence its flight, the preparation for which, in this bird, is slow and laborious. The female lays her eggs on the bare ground, never more than two in number, in a hole scratched by her for the purpose; and if these are touched or soiled during her occasional absence, she immediately abandons them. The male is distinguished by a large pouch, beginning under the tongue, and reaching to the breast, capable of holding, according to Linnæus, seven quarts of water. This is sometimes useful to the female during incubation, and to the young before they quit their nest; and it has been observed to be eminently advantageous to the male bird himself, who on being attacked by birds of prey, has often discomfited his enemies by the sudden and violent discharge of water upon them. These birds are solitary and shy, and feed principally upon grasses, worms, and grain. They were formerly much hunted with dogs, and considered as supplying no uninteresting diversion. They swallow stones, pieces of metal, and other hard substances. Buffon states that one was opened by the academicians of France, which contained in its stomach ninety doubletons, and various stones, all highly smoothed by the attrition of the stomach. The little bustard is met with in many parts of Europe, particularly in France, where it is taken by nets. It is rarely seen in England, is shy and cunning; if molested, will fly about two hundred paces, and then run so fast that a man cannot overtake it. Its flesh is like that of the great bustard, rich and delicate, and it would appear worth while to attempt the domestication of both these birds.

OTTER. See **MUSTELA**.

OUNCE, a little weight, the sixteenth part of a pound avoirdupois, and the twelfth part of a pound troy; the ounces avoirdupois, is divided into eight drachms, and the ounce troy into twenty pennyweights.

OUNCE. See **FELIS**.

OUTFIT, implies the expenses of equipping a ship out for sea.

OUT OF TRIM, the state of a ship when she is not properly balanced for the purposes of navigation, which may be occasioned by a defect in the rigging, or in the stowage of the hold.

OUTLAWRY, the punishment of a person who being called into law, and lawfully sought, according to the usual forms, does contemptuously refuse to appear. The effect of being outlawed at the suit of another, in a civil case, is the forfeiture of all the outlaw's goods and chattels to the king, and the profits of his lands while the outlawry is in force.

OUTLICKER, a small piece of timber made fast to the top of the poop, and standing out right astern.

OUTRIGGER, a strong beam of timber, of which there are several, fixed on the side of a ship, and projecting from it, in order to secure the masts in the act of careening, by counteracting the strain it suffers from the effort of the careening tackles, which being applied to the mast head, draw it downwards, so as to act upon the vessel with the power of a lever, whose fulcrum is in her centre of gravity.

OUTRIGGER, is also a small boom, occasionally used in the tops, to thrust out the breast backstays to windward, in order

ase the angle of tension, and thereby give an additional to the topmast. It is usually furnished with a tackle inner end, communicating with one of the topmast, and has a notch on the outer end to contain the back- id keep it steady therein. As soon as the backstay is tight by means of its tackles in the chains, the outrigger aloft, which it forces out to windward, beyond the f the top, so as to increase the angle which the mast with the backstay, and accordingly enables the latter to support the former. This machine is sometimes without any tackle; it is then thrust out to its usual dis- eyond the top rim, wherein it is securely fastened; after the backstay is placed in the notch, and extended below. WARD, in Navigation, implies out of the port, or king- , "the outward-bound ships, as by my last letter."

WORKS, in Fortification, all those works made with- the ditch of a fortified place, to cover and defend it. ks, called also advanced and detached works, are those not only serve to cover the body of the place, but also the enemy at a distance, and prevent his taking ige of the cavities and elevations usually found in the about the counterscarp, which might serve them either ments, or as rideaux, to facilitate the carrying on their s, and planting their batteries against the place; such lines, tenailles, horn-works, velopes, crown-works, &c. L, an oblong curvilinear figure, having two unequal dia- and bounded by a curve line returning into itself. Un- general definition of an oval is included the ellipse, a regular oval; and all other figures which resemble se, though without possessing its properties, are classed he same general denomination.

ave shewn under the article ELLIPSE, different mechanical s of describing ellipses; and we shall therefore only this place a practical method of describing an oval, o the eye very much resembles the conical ellipse; this lows:—Set the given length AB angles to the breadth CD, so ey bisect each other perpendi- at E; with the centre C and AE describe an arc to cross F and G, and with the radii l BG, describe two little arcs, and KL for the smaller ends oval; and then with centres C and D, and radius CD, e the arcs HCK and IDL, for the flatter or larger arcs gure.

RBLOW, is when the wind blows so very hard that can bear no top-sails.

RBOARD, the state of being thrown out, or the act g from a ship or boat into the water on which she as, there is a man overboard,—he threw her guns rd, &c.

CAST Staff, a scale or measure, employed by ship- to determine the difference between the curves of imbers, which are placed near the greatest breadth, se which are situated near the extremities of the keel, the floor rises and grows narrower.

RGROWN, is said of the sea when the surges and are unusually high; but when the waves are no more mmonly high, it is called a rough sea.

RHAULING, the act of opening and extending the parts of a tackle or other assemblage of ropes, com- ting with blocks or dead-eyes, so that they may be placed in a state of action.

OVERHAULING, also implies an examination of a ship, per- thing. One ship is said to overhaul another, when ns fast upon her in chase.

RMASTED, the state of a ship whose masts are too r too heavy, for the weight of her keel to counterbalance. RRAKE, when a ship rides at anchor in a head sea, ves of which frequently break in upon her, they are said take her.

IRSEERS OF THE POOR. By 43 Elizabeth, c. 2, § 1, the wardens of every parish, or two substantial householders, nominated yearly within fourteen days after the 25th ch, under the hand and seal of two justices of the peace

of the county, shall be overseers of the same parish. In gen- eral, all persons are liable to serve, with some exceptions as to peers of the realm, clergymen, parliament men, attorneys, practising barristers, the president and members of the college of physicians, surgeons, and apothecaries free of the hall; dissenting ministers, prosecutors of felons having a Tyburn ticket, and soldiers actually serving in the militia. In exten- sive parishes, a great number of overseers are appointed under 13 and 14 Charles II. c. 12, § 21; and by 17 George II. c. 38, if an overseer dies, removes, or becomes insolvent, the justices may appoint another, and their appointment is subject to appeal to the sessions. By 43 Elizabeth, c. 2, § 2, overseers shall within fourteen days after the appointment of new ones, deliver to them an account to be allowed by two justices, and pay over balances due from them, which, if not paid, may be levied by distress, and the party committed to prison by the justices until the balance is paid, and the account delivered in; and by 17 George II. c. 38, the account is to be verified by oath. If he removes, the overseer is to account in like man- ner. If he dies, his executors have forty days to account, and must pay the balance before any other debts. Their duty con- sists in raising the poor's-rates, taking care of the poor, giving relief to casual poor, and removing improper persons who have become actually chargeable and have no legal settlement. They are also to bind out the children of poor persons, and in that case the infant parish apprentice and his master cannot vacate the indentures without the overseers. They are also to pro- cure orders of maintenance of bastards to be made, and bonds to be taken from the reputed father to indemnify the parish. It has been usual for overseers in those cases, instead of taking a bond of indemnity, to accept of a sum of money, and discharge the father. But this has been lately held to be illegal, because it gives the overseers an interest to procure the death of the child. In cases of removal also, overseers should be careful not to execute the order in a harsh and improper manner, for if a person die in consequence of a removal at a time of sick- ness, the overseer may be guilty of murder, and liable to an indictment. Overseers also should not improperly conspire to force persons who are with child of bastards, to marry and relieve the parish, for this also is indictable. By 17 George II. c. 38, if any person shall be aggrieved by any thing done or omitted by the churchwardens and overseers, or by any of his majesty's justices of the peace, he may, giving reasonable notice to the churchwardens or overseers, appeal to the next general or quarter sessions, where the same shall be heard, or finally determined; but if reasonable notice be not given, then they shall adjourn the appeal to the next quarter sessions; and the court may award reasonable costs to either party, as they may do by 8th and 9th William, in case of appeals concerning settlements. See POOR. By 43 Elizabeth, c. 2, § 2, they forfeit 20s. on neglecting to meet in the vestry one Sunday in the month; and by 13 and 14 Charles II. c. 4, forfeit £5 for refus- ing relief to a person duly removed by warrant of two justices. By 9 George III. c. 37, § 7, they are to forfeit 10s. or 20s. for paying the poor in bad money.

OVERSETTING, the act of turning any thing upside down: also the movement of a ship when her keel turns upwards; which misfortune happens either by hearing too much sail, or by grounding her so that she falls on one side.

OVERT, the same with open. Thus an overt act signifies an act which, in law, must be clearly proved; and such as is to be alleged in every indictment for high treason.

OVIS, Sheep, a genus of the order pecora, usually the most timid of quadrupeds. When sheep, however, have an exten- sive range of pasture, and are left in a considerable degree to depend upon themselves for food and protection, they exhibit more respectability of character. A ram has been seen in these circumstances to attack and beat off a large and formid- able dog, and even a bull has been felled by a stroke received between his eyes, as he was lowering his head to receive his adversary on his horns, and toss him into the air. When individual efforts are unequal to the danger, sheep will unite their exertions, placing the females and their young in the middle of an irregular square; the rams will station themselves so as to present an armed front on every side to the enemy, and will support their ranks in the crisis of attack, harassing

the foe by the most formidable and sometimes fatal blows. Sheep display considerable sagacity in the selection of their food, and in the approach of storms they perceive the indications with accurate precision, and retire for shelter always to the spot which is best able to afford it. The domestic sheep is scarcely ever found (excepting in temperate latitudes) in a state approaching to perfection. In hot regions its wool degenerates into a species of hair, and in rigid climates, though the wool is fine at the root, it is coarse towards the surface.

OWNER, the proprietor of any thing, as of a ship, by whom she is freighted to the merchant for a sea voyage.

OX, in Zoölogy, is a generic term, synonymous with *Bos*, including both the male and female. Few species, however, of this tribe appear to be really distinct. Their variations arise from climate, domestication, and other causes, which it would be tedious to enumerate. In modern language, the word ox is confined to the male species of neat cattle that have undergone mutilation by the hands of man. In this sense, the animal is too well known to require any particular description, either of its natural history, its formation, or its utility.

OXALATES. Compounds of salifiable bases with the oxalic acid.

OXALIC ACID. This acid, which abounds in wood sorrel, and which, combined with a small portion of potash, as it exists in that plant, has been sold under the name of salt of lemon, to be used as substitute for the juice of that fruit, particularly for discharging ink spots and iron-moulds, was long supposed to be analogous to that of tartar. The oxalic acid is a good test for detecting lime, which it separates from all the other acids, unless they are present in excess. It has likewise a greater affinity for lime than for any other of the bases, and forms with it a pulverulent insoluble salt, not decomposable except by fire, and turning syrup of violets green. Oxalic acid acts as a violent poison when swallowed in the quantity of two or three drachms; and several fatal accidents have lately occurred, in consequence of its being improperly sold instead of Epsom salts. The immediate rejection from the stomach of this acid, by an emetic, aided by copious draughts of warm water containing bicarbonate of potash, or soda, or chalk, or carbonate of magnesia, are the proper remedies. The stomach pump has of late been successfully used in discharging this poison. See *SYRINGE*.

OX-EYE, a small cloud or meteor, seen at the Cape of Good Hope, which presages a dreadful storm. It appears at first in the form or size of an ox's eye, but descends with such celerity, that it seems suddenly to overspread the whole hemisphere, and at the same time forces the air with such violence that ships are sometimes scattered several ways, some directly contrary, and many sunk downright.

OXGANG, or **OXGATE**, is generally taken, in our old law books, for fifteen acres, or as much ground as a single ox can plough in a year.

OXIDATION. The process of converting metals, or other substances, into oxides, by combining with them a certain portion of oxygen. It differs from acidification, in the addition of oxygen not being sufficient to form an acid with the substance oxidized.

OXIDE, CARBONIC. When a mixture of purified charcoal and oxide of iron or zinc is exposed to a strong heat in an iron retort, the metallic oxide is gradually reduced, and, during the reduction a great quantity of gas is evolved. This gas is a mixture of carbonic acid gas, and another which burns with a blue flame. This last is carbonic oxide.

OXIDES. Substances combined with oxygen, without being in the state of acid.

OXYDE, or **OXIDE**, a chemical term denoting a very numerous class of bodies, formed by the union of certain bases, with a smaller proportion of oxygen than what is necessary for their conversion into acids. Metals oxydize by combustion, solution in acids, and exposure to the air, rain, &c. as in the case of rust of iron, which is an oxide.

OXYGEN, is a constituent part of the atmospheric air, of water, of acids, and of all bodies of the animal and vegetable kingdoms; combined with light and heat, and as oxygen gas, it approaches nearest to purity. Oxygen is only known in combination with other bodies and has not been obtained

alone. When absorbed by combustible bodies, it converts them into acids. It is necessary to combustion, uniting itself always to bodies which burn, augmenting their weight, and changing their properties. It is necessary also to the respiration of animals. To procure oxygen gas, a quantity of manganese is produced into a glass retort, furnished with a ground stopper; a quantity of oil of vitriol (sulphuric acid,) sufficient to moisten the manganese, is added, and they are mixed together by means of a glass rod; the bottom of the retort is then gently heated by means of a lamp, and the extremity of its neck introduced under an inverted cylinder, filled with water in the hydro-pneumatic apparatus. Globules of gas will soon rise through the water; the first portions collected must be thrown away, being principally the common air contained in the retort; when a quantity equal to the capacity of the retort has been thus disposed of, the remainder may be preserved for use. There are many other modes of obtaining oxygen gas; the same manganese, heated to redness in an iron tube, such as a gun-barrel, the touch-hole of which is closed, will afford a considerable quantity of the substance, which may be collected by means of a tube fastened into the neck of the barrel, and having its extremity in the hydro-pneumatic apparatus. Nitre heated strongly in a porcelain retort, gives off oxygen gas: puce-coloured or red oxide of lead offers a similar result; and from any of the salts called hyper-oxymuriates, oxygen is procured by a dull red heat; a retort of glass may be employed in the process; and a charcoal fire in a small chafing-dish. One hundred grains of the hyper-oxymuriate of potassa, afford about one hundred and fourteen cubical inches of oxygen gas, under common circumstances. Oxygen gas may be procured in the hydro-pneumatic apparatus from zinc or iron filings, by means of oil of vitriol diluted with eight times its weight of water; a retort, or a bottle furnished with a tube, may be used; no artificial heat is required in the process. It may likewise be produced by passing steam over turnings of iron heated to redness in a gun-barrel. Oxygen gas, combined with hydrogen, forms water; with nitrogen, common atmospheric air; with sulphur, phosphorus, &c. sulphuric acid, phosphoric acid, &c.; alone it has neither smell nor taste. Oxygen gives the sharp, acrid character to those which are called acids. It combines with metals, destroys their metallic lustre, and gives them an earthy or *rusty* appearance. These substances are called oxides, and they are all heavier than the metals from which they are formed. Oxygen readily enters into combination, and no substance is more active as a chemical agent. It is known to be a constituent part of most of the acids and earths, and of all the alkalies except one, and the history of its compounds forms the most extensive and important part of modern chemistry. The operations of oxygen are connected with many of the arts; with the processes of bleaching, dying, colour-making, and metallurgy; and in its various applications to the production of fire, it is absolutely essential to cultivation, and to the comforts and enjoyments of social life.

OXYMEL. A compound of honey and vinegar.

OXYMURIATES. Compounds of the chloric acid with salifiable bases. The oxymuriate of mercury is corrosive sublimate. The oxymuriate or chloride of alumina has been used in discharging Turkey red.

OXYMURIATIC ACID GAS. See *CHLORINE*.

OYER OF DEED, is when a man brings an action upon a deed, bond, &c. and the defendant appears, and prays that he may hear the bond, &c. wherewith he is charged, and the same shall be allowed him; and he is not bound to plead till he has it, paying for the copy of it. The time allowed for the plaintiff to give oyer of a deed, &c. to the defendant, is two days exclusive after it is demanded. Carth. 454. 9 Durnf. and East. 40.

OYER AND TERMINER, is a court held by virtue of the king's commission to hear and determine all treasons, felonies, and misdemeanors. This commission is usually directed to two of the judges of the circuit, and several gentlemen of the county; but the judges only are of the quorum, so that the rest cannot act without them. 4 Black. 269. See *ASSIZES*.

O YES, corrupted from the French *oyez*, hear ye; is an expression used by the crier of a court, in order to enjoin silence when any proclamation is made.

P.

P, as an abbreviation, among Astronomers, stands for *post*, after; as *P M. post meridian*, i. e. after 12 at noon. **P**, with physicians, signifies *pugil*, a handful, or *pulvis*, powder.

PABULUM OF PLANTS. No one principle affords the pabulum of vegetable life; it is neither charcoal, nor hydrogen, nor azote, nor oxygen, alone; but all of them together, in various states and combinations.

PACE, two and a half feet; but the geometrical pace is 5 feet, and 60,000 such paces make one degree of the equator.

PACE, in the Manege, is of three kinds, the walk, trot, or gallop. **PACK**, in Commerce, is a horse's load; as, a pack of wool, which is 17 stone 2lbs. Hence from pack, we have—

PACKAGE, the duty of one penny in the pound paid for all goods not particularly rated.

PACKERS, persons whose employment it is to pack up all goods intended for exportation; which they do for the great trading companies and merchants of London, and are answerable if the goods receive any damage through bad package.

PACKET BOAT, a vessel appointed by government to carry the mail of letters, packets, and expresses, from one part of the kingdom to another by sea, or to the colonies, in the most expeditious manner. This service is now very expeditiously executed by the *steam packets*.

PACOS. See *CAMELUS*.

PADDOCK COURSE, a piece of ground with pales or a wall, and taken out of a park for exhibiting races with greyhounds, for plates, wagers, and the like. This area is generally a mile in length and a quarter of a mile broad.

PADDOCK, in Agriculture, signifies nothing more than a small field or enclosure. It is also a name given to a large toad or frog.

PÆDEROTA, a genus of plants, of the pentandria class; and in the natural method ranking with the 30th order, contortæ.

PÆONIA, *PIONY*, a genus of plants belonging to the polyandria class; and in the natural method ranking under the 26th order, multisiliquæ.

PAGAN, from the Latin *pagus*, a villager, not a citizen.

PAGAN, BLAISE FRANÇOIS COMTE DE, a very eminent French mathematician and engineer, was born at Avignon in Provence, in 1604, and died in 1665, in the sixty-first year of his age. Pagan was most distinguished in his military character, and for the works which he wrote on the theory of fortification; but his other performances are also very honourable testimonies of his scientific acquirements.

PAGANISM, the religion of the heathen nations, in which the Deity is represented under various forms, and by all kinds of images, or idols; it is therefore called idolatry, or image worship. The theology of the pagans was of three sorts, viz. fabulous, natural, and political or civil. The first treats of the genealogy, worship, and attributes of their deities; who were for the most part the offspring of the imagination of poets, painters, and statuary. To their gods were given different attributes, ascribing to them every species of vice, as well as to some of them every virtue.

PAGE, a youth of state, retained in the family of a prince or great personage, as an honourable servant to attend in visits of ceremony, carry messages, bear up trains, robes, &c. and at the same time to have a genteel education, and learn his exercises.

PAGOD, or *PAGODA*, a name whereby the East Indians call the temple in which they worship their gods. The pagod usually consists of three parts; the first is a vaulted roof, supported on stone or marble columns; it is adorned with images; and being open, all persons without distinction are allowed to enter it. The second part is filled with grotesque and monstrous figures, and no person is allowed to enter it but the brahmins themselves. The third is a kind of chancel, in which the statue of the deity is placed. It is shut up with a very strong gate.

PAGOD, or *Pagoda*, is also the name of a gold or silver coin, current in several parts of the East Indies, value 5s.

PAIN, an uneasy sensation, arising from a sudden and violent solution of continuity, or other accident, in the nerves, membranes, vessels, &c. From the sense of feeling, as well as all the other senses, either pain or pleasure may arise; nay, to this sense we commonly refer both pain and almost all other troublesome sensations, though in truth pain may arise from every vehement sensation. It is brought on by any great force applied to the sentient part; whether this force comes from within or from without. Whatever therefore pricks, cuts, lacerates, distends, compresses, bruises, strikes, gnaws, burns, or in any manner of way stimulates, may create pain. Hence it is so frequently conjoined with so many diseases, and is often more intolerable than even the disease itself. A moderate degree of pain stimulates the affected part, and by degrees the whole body; produces a great flux of blood to the part affected, by increasing the action of its vessels; and it seems also to increase the sensibility of the part affected to future impressions. It often stimulates to such motions as are both necessary and healthful. Hence, pain is sometimes to be reckoned among those things which guard our life. When very violent, however, it produces too great irritation, inflammation, and its consequences, fever, and all those evils which flow from too great force of the circulation; it disorders the whole nervous system, and produces spasms, watching, convulsions, delirium, debility, and fainting. Neither the mind nor body can long bear very vehement pain; and indeed nature has appointed certain limits, beyond which she will not permit pain to be carried, without bringing on delirium, convulsions, syncope, or even death, to rescue the miserable sufferer from his torment. Long continued pain, even though in a more gentle degree, often brings on debility, torpor, palsy, and rigidity of the affected part. But if not too violent, nor accompanied with fever, sickness, or anxiety, it sometimes seems to contribute to the clearness and acuteness of the judgment, as some people testify who have been afflicted with the gout.

PAINTING, is the art of representing all objects of nature visibly, by lines and colours, on a plain surface; and may be divided into Invention, Composition, Design, and Colouring. See *DRAWING*.

Invention consists generally in the choice of such subjects as are best calculated to answer some great and interesting end.—Composition regards the arrangement of the subject both as to forms, and to the general effects of light and shade, and of colour.—The important objects which Design embraces, will be found under that article. See *DESIGN*.

Colouring regards first, the infinite variety of hues with which nature distinguishes her forms, agreeably to the degree and mixture of the rays of light which their surfaces reflect; and secondly, the distribution, apposition, and accompaniment, of various hues or tints, to produce the effect most pleasing to the sight, a circumstance in which nature does not always delight.

Colouring.—It is the duty of the colourist to consider, that as there are two sorts of objects, the natural or real, and the artificial or painted; so there are also two sorts of colours, viz. the natural, or that which makes all the objects in nature visible to us; and the artificial, or that which, by a judicious mixture of simple colours, imitates those natural ones in all their various situations and circumstances. Several colours which, placed unmixed by one another, have a kind of aerial brightness, when mixed together produce a disagreeable earthy colour; for instance, ultramarine with fine yellow, or fine vermilion. Colours, which by mixture lose strength and become harmonious, are called broken colours, and contribute as greatly to the sweetness and softness of tones in pictures, as they subtract from their brightness.

Chiaro Scuro.—The art of chiaro-scuro consists, 1st. In connecting and combining the figure or objects of a composition in such masses of light and of shade as are both the most pleasing to the eye, and best calculated for the just development and display of the subject. 2d. In assigning to each object the

colour most corresponding (on account of the force or qualities above mentioned) to its respective place in the general mass or group, and at the same time best harmonizing with the other colours of the picture, either by its natural and proper tone, or by the reflected hues which it receives from adjoining or surrounding objects. The beauty of these reflexes depends on the skilful adaptation of transparent or opaque colours. 3d. In the judicious introduction of such accidents as contribute to strengthen the general effect and character of the work.

Composition.—Composition may be divided into the general distribution of objects, the grouping, the choice of attitudes, the contrast, the cast of draperies, and the management of the back ground, or the connexion of the whole effect. In composition, as far as regards the general distribution of objects, the painter ought to contrive, that the spectator may, at the first sight, be struck with the general character of the subject, or at least may comprehend its principal scope. This effect is most readily produced, by placing the most essential figures in the most conspicuous places, provided it can be done without violence or impropriety. Besides this distinctness in the general expression of the subject, the beauty of the composition will depend on the variety, connexion, and contrast, displayed in the distribution of objects; provided, in like manner, that these are conformable to the nature of the subject, whether gay, familiar, full of motion and hurry, or still, solemn, and melancholy. The grouping regards both design and chiaro-scuro. In the former, it respects the figures principally concerned in the expression of the subject, which must necessarily be near to or distant from one another, as their actions, conversations, or other mutual relations, require. In the latter, it regards those masses which are formed from objects which may be properly arranged together, and those effects of light and shade which are formed in consequence of such assemblage or union. These are the points to which the attention must be principally and diligently directed in forming the groups of a composition. The choice of attitude is the principal subordinate division of grouping. Whatever attitude is given, it must not only contribute its due portion to the completion of the group, but the greatest care must be taken by the painter, that it does not appear to be introduced for that purpose merely. It must be appropriate to the character of the individual figure, and expressive of its requisite action; and it must at the same time combine whatever beauty of form can be shewn by such a selection of turns or views of the body, as the necessary circumstances will admit. The knowledge of generic characters, under the various modifications of sex, age, and condition; of the various operations of the passions in the human mind; and a thorough acquaintance with the circumstances of the history, or other subjects to be represented, are the best guides to a good choice of attitudes.

Of the different Classes of Painting.—Painting is chiefly divided into historical, (comprehending allegorical and mystical,) grotesque, portrait, fancy, animals, fruits and flowers, battles, landscape, sea views, architecture, and still life. The subordinate divisions of all these are endless. Grotesque paintings are to be found in the celebrated Loggia of the Vatican palace at Rome, painted from the designs of Raffaele, and in the ceiling of the portico of the Capitol, carved from those of Michael Angelo. Of portrait, as being a branch of painting to which our country is peculiarly addicted, it is requisite to give a more detailed account.

Portraiture.—The greatest perfection of a portrait is extreme likeness, and the greatest fault is the resemblance of a person for whom it was not designed, unless we are inclined to except a still more grievous defect, viz. the want of resemblance to any person whatever.

The different modes of painting now in use are:—Oil painting; preferable to all other methods, as it admits of a perfect gradation of the tints in the most durable of all materials, except those of Mosaic painting. Fresco painting; which is performed with colours diluted in water, and laid on a wall newly plastered, with which they incorporate, and are sometimes as durable as the stucco itself. Crayon painting; in which colours, either simple or compound, are ground in water mixed with gum, and made into small rolls of a hard paste, which are then used on paper or parchment. Miniature paint-

ing; which consists of colours prepared with water or gum, and laid on vellum or ivory. Enamel painting; which is performed on copper or gold, with mineral colours, dried by fire. This method is also very durable. Wax, or encaustic painting; performed by the mixture of wax with the varnish and colours. Painting on glass, too well known to need description, and performed by various methods. Painting in distemper; which is with colours mixed with size, white of eggs, or any thin glutinous substance, and used on paper, linen, silk, board, or wall. Painting in water colours, more properly called limning: it is performed with colours mixed with water, gum, size, paste, &c. on paper, silk, and various materials. To these is to be added elydoric painting, consisting of a mixed use of oil colours and waters.

Method of Painting in Fresco.—Before you begin to paint, it is necessary to apply two layers of stucco on the place where your work is to be executed. If you are to paint on a wall of brick, the first layer is easily applied; if of freestone closely joined, it is necessary to make excavations in the stone, and to drive in nails or pegs of wood, in order to hold the layer together. The first layer is made of good lime and a cement of pounded brick, or, which is better, river sand, which latter forms a layer more uneven, and better fitted to attach the second smooth layer to its surface. When the first layer is perfectly dry, wet it again with water, in proportion to its dryness, that the second layer may more easily incorporate with it. The second layer is composed of lime, slaked in the air, and exposed for a whole year, and of river sand of an equal grain, and moderately fine. The surface of this second layer must be uniformly even. To give a fine polish to this surface, a sheet of paper should be applied on it, and the trowel passed and repassed over the paper. The workman must not extend the layer over a greater space than the painter is able to finish in a day, as it is necessary that the ground should always be fresh and moist under his pencil. The ground being thus prepared, the painter begins his work; but as painting in fresco must be executed rapidly, and as there is not time to retouch any of the strokes of the brush with good effect, he will first have taken care to provide himself with large finished drawings in chalk, or paintings in distemper, of the same size as the work which he has to paint, so that he shall have only to copy these drawings on the wall. The painter traces the outlines of the figures on the plaster, by passing a steel point over them, or pricking them closely, and passing very finely powdered charcoal through the pricked holes. All natural earths are good for painting in fresco. The colours are ground, and tempered with water. It is to be remarked, that all the colours used in this method of painting brighten as they grow dry, excepting the pavonazzo, or red varnish, the brownish red ochre, ruth ochre, and the blacks, particularly those that are passed through the fire.

The best colours are white, made of old lime and white marble dust, (the proportional quantity of the latter depends on the quality of the lime, and must be found by trial, as too great a quantity of marble dust will turn the colour black,) ultramarine blue, the black of charcoal, yellow ochre, burnt vitriol, red earth, green of Verona, Venetian black, and burnt ochre. Other colours, which require to be used with greater precaution, are amel, or enamel blue, and cinnabar. Enamel blue must be applied instantaneously, and while the lime is very moist, otherwise it will not incorporate; and if you retouch with it, you must do it an hour or more after the first application of it, in order to increase its lustre. Cinnabar has a splendour almost beyond all other colours, which it loses when mixed with lime. It may, however, be employed in places not exposed to the air, if carefully prepared. For this purpose, reduce a quantity of the purest cinnabar to powder, put it into an earthen vessel, and pour lime water on it two or three times. By this process the cinnabar receives some impression from the lime water, and you may then use it with greater safety. The white of lime is formed by mixing lime, slaked a long time before, with good water. The lime deposits a sediment in the vessel, when the water is poured off; this sediment is the white of lime. Ochres of all kinds make good colours for fresco, being previously burnt in iron boxes. Ultramarine never changes, and seems to communicate its permanent quality to the colours with which it is mixed.

Distemper.—Until the discovery of oil-painting, the methods most generally adopted by all Italian painters were those of distemper and fresco. In distemper, when they painted on boards, they often pasted over the boards a piece of fine cloth, to prevent them from parting; they then laid on a layer of white, after which, having tempered their colours with water and paste, (or rather with water and yolks of eggs beat together with little fig-tree branches, the milk of which they mixed with the eggs,) they painted their picture with this mixture. All colours are proper for distemper, except the white of lime, which is used in fresco only.

Oil Painting.—The principal advantage of oil painting over other methods, consists in the colours drying less speedily, so that it allows the painter to finish, smooth, and retouch his works with greater care and precision. The colours also being more blended together, produce more agreeable gradations, and a more delicate effect.

Of Painting Flesh.—Principal colours from which all the tints of the flesh are made, and their qualities in painting: Flake white is the best white known to us. This colour should be ground with the finest poppy oil that can be procured. White comes forward to the eye with yellows and reds, but retires with blues and greens. It is the nature of all whites to sink into whatever ground they are laid on, therefore they should be laid on white grounds. Ivory black is the best black; it is a colour which mixes kindly with all the others. It is the true shade for blue; and when mixed with a little Indian red, it is the best general shadow colour that can be used. It is generally ground with linseed oil, and used with drying oil. Black is a cold, retiring colour. Ultramarine is the finest blue in the world: it is a tender retiring colour, and never glares, and is a beautiful glazing colour. It is used with poppy oil. Lake is a tender deep red, but of no strong body; therefore it should be strengthened with Indian red. It is the best glazing colour that can be used. It is ground with linseed oil, and used with drying oil. Burnt umber is a fine warm brown, and a good working strong colour; it is of great use in the hair, and mixes finely with the warm shade.

Process.—The process of oil painting, particularly in the colouring of flesh and in landscape, is to be divided into three stages, or paintings. The colours and tints necessary for the first and second stages of painting flesh, are; 1, flake, or fine white; 2, light ochre and its tints; 3, light red and its two tints; 4, vermilion and its tint; 5, a tint composed of lake, vermilion, and white; 6, rose tint; 7, blue tint; 8, lead tint; 9, green tint; 10, half shade tint, made of Indian red and white; 11, shade tint; 12, red shades; 13, warm shade. The finishing tincture for a complexion requires 5 more: 1, carmine and its tints; 2, lake; 3, brown pink; 4, ivory black; 5, Prussian blue.

First Stage, or Dead Colouring of Flesh.—The first lay of colours consists of two parts; the one is the work of the shadows only, and the other that of the lights. The work of the shadows is to make out all the drawing very correctly with the shade tint, in the same manner as if it was to be done with this colour only, and remember to drive or lay the colour sparingly. The lights should be all laid in with the light red tint, in different degrees, as we see them in nature. These two colours united, produce clean, tender, middle tint. In uniting the lights and shades, we should use a long softener, about the size of a large swan quill, which will help to bring the work into character, and give the colouring more delicate; then go over the darkest shadows with the red or warm shade, which will finish the first lay. The warm shade being laid on the shade tint, improves it to a warmer hue; but if laid instead of the shade tints, it will dirty and spoil the colours it mixes with; and if the red shade is laid first instead of the shade tint, the shadows would then appear too red; therefore, notwithstanding these two colours are the best that can be for the shadows, yet they are too strong to be laid alone, which is a proof of the great use and merit of the shade tint. Here we may observe, that the shade and light red tints are so friendly in their nature, than even in continually altering and changing, they always produce a clean colour of a nearly hue.

Next.—In order to finish the first painting, improve the reds and yellows to the complexion, and after them the blues; observing that the blues on the reds make the purple, and on the

yellows produce the green. The same method is to be understood of the shadows; but be sure to leave them clean, and not too dark; therefore allowance should be made in the grounds with the light red, because glazing them will make them darker. When the cloth is of a dark or bad colour, there must be a strong body of colour laid all over the shadows, such as will not sink into the ground, but appear warm, and a little lighter than the life, so that it may be of the same forwardness to finish as if it had been a light ground; therefore the business of dead-colouring is, that you leave it always in the same order for finishing, though the colour of the cloth is quite the reverse.

Second Painting, or Second Stage.—The second painting begins with laying on the least quantity that can be of poppy-oil; then wipe it almost all off, with a dry piece of a silk handkerchief. The second painting is also divided into two parts: one the first lay of the second painting; which is scumbling the lights, and glazing the shadows; the other, finishing the complexion with the virgin tints, and improving, as far as you can without daubing.

First.—Scumbling is going over the lights where they are to be changed, with the light red tints or some other of their own colours, such as will always clear and improve the complexion, with short stiff pencils, but such parts only as require it, otherwise the beauty of the first painting will be spoiled. The light red tint improved is the best colour for scumbling and improving the complexion in general. Where the shadows and drawing are to be corrected, you should do it with the shade tint, by driving the colour very stiff and bare, that you may the easier retouch and change it with the finishing tints. Some parts of the shadows should be glazed with some of the transparent shadow colours, such as will improve and come very near to the life; but be sure not to lay on too much of it, for fear of losing the hue of the first painting, the ground of which should always appear through the glazing. Be very careful, in uniting the lights and shades, that they do not mix dead and meanly; for the more the lights mix with the shades, the more meanly the shades will appear. Thus far the complexion is prepared and improved, in order to receive the virgin tints.

Third Painting, or Finishing.—It is to be supposed the complexion now wants very little more than a few light touches; therefore there will be no occasion for oiling. Begin with correcting all the glazing first, where the glazing serves as a ground or under part; then determine what should be done next, before you do it, so that you may be able to make the alteration on the part with one stroke of the pencil. By this method you preserve both the glazing and the tints; but if it happens that you cannot lay such a variety of tints and finishing colours as you intended, it is much better to leave off while the work is safe and in good order; because those few touches, which would endanger the beauty of the colouring, may easily be done, if you have patience to stay till the colours are dry; and then, without oiling, add those finishings with free light strokes of the pencil.

Of Painting Draperies.—The right method of painting draperies in general, is to make out the whole or the first lay with three colours only, viz. the lights, middle tint, and shade tint. In the first lay, the high lights should be laid with plenty of stiff colours and then shaped and softened into character with the middle tint very correctly. Where the gradations of the lights are slow, as in the large parts, it will be proper to lay the middle tint first at their extremities, with a tool that will drive their colour, and leave it sparingly; because the lights will mix and lie the better upon it. Next make out all the parts of the shadows with the tint driven bare. After this comes the middle tint, for the several lights and gradations; which should be very nicely wrought up to character without touching any of the high lights which finish the first lay. The reflects and finishings tints are in general the antipathies of the first lays; they will, without great care, dirty the colours on which they are laid, and therefore should be laid with a delicate light touch, without softening. If it is overdone, endeavour to recover it with the colour of the part on which it was laid; this may be done directly, or when it is dry. Whether the reflects proceed from the same colour, or any other, the method of using them is the same. It often happens that the colour of the cloth is very

native cinabar; 14. King's yellow. The principal tints are, 1. Light ochre, and white; 2. Light ochre, Prussian blue, and white; 3. Light ochre and Prussian blue; 4. The same darker; 5. Terreverte and Prussian blue; 6. Brown pink and Prussian blue; 7. Brown pink and brown ochre; 8. Brown pink, ochre, and Prussian blue; 9. Indian red and white; 10. Ivory black, Indian red, and lake. The colours necessary for dead colouring are: common white, light ochre, brown ochre, burnt umber, Indian red, ivory black, and Prussian blue. The principal colours and tints for painting the sky are, fine white, ultramarine, Prussian blue, light ochre, vermilion, lake, and Indian red. The tints are, a fine azure, lighter azure, light ochre, and white vermilion and white; and a tint made of white, a little vermilion, and some of the light azure at your discretion.

Process.—Sketch or rub in your design faintly, with burnt umber used with drying oil, and a little oil of turpentine, leaving the colour of the cloth for the lights. Remember, in doing this, to leave no part of the shadows so dark as you intend the first lay or dead colouring, which also is to be lighter than the finishing colours. Though the foliage of the trees is only rubbed in faintly, yet the trunks and bodies should be in their proper shapes, with their breadths of light and shadows. All kind of buildings should be done in the same manner, leaving the colour of the cloth for their lights. The figure on the fore ground may also be sketched in the same manner, and then left to dry.

First Painting, or Dead Colouring.—Let the first lay or dead colouring be without any bright, glaring, or strong dark colours; so that the effect is made more to receive and preserve the finishing colours, than to shew them in their first painting. The sky should be done first, then all the distances; and so work downwards to the middle group, and from that to the fore ground, and nearest parts. Remember, all the parts of each group, as trees, buildings, or the like, are all painted with the group they belong to. The greatest secret in dead colouring is to find the two colours which serve for the ground of shadows in general, the sky excepted; and the method of using them with the lights, the first of which is the dark shade with a little lake in it; the other colour is only burnt umber. These should be a little changed to the natural hue of the objects, and then laid on with drying oil in the same manner as we shade with Indian ink, which is a kind of glazing, and as such they should be left, otherwise they will be dark and heavy, and therefore would be entirely spoiled for the finishing glazing. Both these colours mix and sympathize agreeably with all the lights, but should be laid before them.

The Sky.—The sky should be laid with a good body of colours and left with a faint resemblance of the principal clouds, more in the manner of claro-obscure than with finishing colours; the whiter it is left, the better it will bear out and support them; the distances should be made out faint and obscurely, with the dark shades and some of their lights in different degrees, and laid so as best to find and shew their principal parts. All the grounds of the trees should be laid or rubbed in, enough only to leave an idea of their shapes and shadows faintly. The ground of their shadows must be clean, and lighter than their finishing colours. In painting the lights, it is better to incline more to the middle tint, than to the very high lights; and observe to leave them with a sufficient body of clean colours, which will preserve the finishing colours better; all which may be done with a few tints. After this, go over the whole with a sweetener very lightly, which will soften and mix the colours agreeably for finishing.

Second Painting.—Begin with the sky, and lay in all the azure, and colours of the horizon; then soften them; after that lay in the general tint of the clouds, and finish on it with the high lights and the other tints that are wanting, with light tender touches; then soften the whole with a sweetener very lightly. The finishing of the sky should be done all at one painting, because the tender character of the clouds will not do so well as when the whole is wet. Observe, that the stiffer the azure and colours of the horizon are laid, the better the clouds may be painted upon them.

Third and last Painting.—If oiling is necessary, lay the least quantity that can be; which should be done with a stump tool or pencil, proportioned to the place that is to be oiled, so as to

oil no more than is wanted: then wipe the whole place that is oiled, with a piece of silk handkerchief. When going to finish any objects, remember to use a great variety of tints, very nearly of the same colour, but most of all when finishing trees. This gives a richness to the colouring, and produces harmony. The greens will fade, and grow darker; therefore it is highly necessary to improve and force them, by exaggerating the lights, and making an allowance in using them so much the lighter. For the same reason, take great care not to overcharge and spoil the beauty of the glazing; for if you do, it will be dull and heavy, and will consequently grow darker. The method of painting near trees is, to make the first lay very near to nature, though not quite so dark, but more in the degree of a middle tint, and follow it with strengthening the shadows; then the middle tints; and last of all lay the high lights and finishing colours. All this cannot be done as it should be, at one painting; therefore the best way is, to do no more than the first lay with the faint shadows, and leave it to dry. Then begin with improving the middle tints and shadows, and let them dry. The third and last work is, adding all the lights and finishing colours in the best manner you are able. This method of leaving the first and second parts to dry separately, not only makes the whole much easier, and more agreeable, but leaves the colours in the greatest perfection; because most of the work may be done with scumbling and glazing, and some parts without oiling. The lights also may be laid with a better body of colour, which will not be mixed and spoiled with the wet ground. The figures in the landscapes are the last work of the picture; those in the fore-ground should be done first, and those in the distances should be done next; for after the figures in the first and farthest group are painted, it will be much easier to find the proportions of those in the middle parts of the picture. And observe, that the shadows of the figures should be of the same hue, or colour, with those of the group or place they are in.

Qualities of the above Colours when used in Miniature.—*Yellows.* Gall-stone is one of the finest and brightest colours, and a lasting one: but it should be sparingly used in the flesh tints, its brilliancy being apt to overpower all the other colours. Terra Sienna is a bright yellow earth, somewhat of a greasy nature, and is used as a warm yellow; but when burnt, is more beautiful, partaking of three tints, yellow, red, and brown. Nottingham ochre works well, but on account of its heavy qualities must be used with caution. Roman ochre is used with success in miniature painting, as it works, when properly proportioned with gum water, extremely sharp and neat; and being in itself a warm colour, communicates that quality to the tints it is worked in. Naples yellow, although adopted by some artists, is of a sickly hue, and has this very bad quality, that it absorbs all colours that are either worked on it, or mixed with it.

Blues. Ultramarine excels all others in permanency. Prussian blue has no substitute, on account of its strength of effect and transparency. Smalt is so hard that nothing but an agate flag and muller will pulverize it sufficiently. It is not to be depended on for permanency. Indigo is a useful blue, though it must be sparingly used, on account of its extreme depth of colour, nearly approaching to black; the best is called the rock indigo. The way to judge of its qualities is to break it, and, if good, it will have a copperish hue, but if bad, it will be of a dead blackish cast. Chinese vermilion, when good, is a bright red, and useful in miniature pictures, though not to be freely used, its opacity rendering it dangerous to mix much with other colours; but by itself, in touching the parts that require extreme brightness, it is of wonderful service. It is very difficult to find the real kind—the common vermilion, mixed with lake or carmine, being a general substitute; but the spurious and the genuine kind very materially differ in working, the former being thick and heavy, the other the contrary. India red is an excellent colour, not only for touching the deep red parts, but likewise in strong flesh tints, in bright back-grounds, and draperies.

Browns. UMBER is very greasy, and mixes unkindly; but, when burnt, is very useful in many parts of miniature. Terra de Cassel, or Vandyck brown, so called from the very great estimation the inimitable painter of that name held it in, is the

first rich brown in the world; in itself producing a more beautiful colour than can be formed by the junction of any colours whatever.

Ivory.—Of ivory there are various kinds, the distinction of which in this art is of very material consequence. Ivory, newly cut, and full of sap, is not easily to be judged of; the general transparency it exhibits in that state, almost precluding the possibility of discovering whether it is coarse-grained or fine, streaky or the contrary, unless to the artist who, by a long course of experience, is familiarized to it. The best way to discover the quality of it is, by holding it grainways to the light, then holding it up and looking through it, still turning it from side to side, and very narrowly observing whether there are any streaks in it; this you will, unless the ivory is very freshly cut, easily discover; and in this you cannot be too particular. There is a species of ivory which is very bad for painting on, although it has no streaks in it, being of a horny coarse nature, which will never suffer the colours to be thrown out in the brilliant manner a fine species of ivory will; you are, therefore, not only to be cautious in choosing ivory free from streaks, but likewise that which has the finest grain, and close. —Having instructed in the mode of choosing ivory, and having prepared it for painting on, we now proceed to give—

Instructions for Mixing Compound Tints for the Face.—Purple is formed of either ultramarine, Prussian blue, smalt, or indigo, mixed with either carmine or drop lake. Ultramarine, although the most beautiful and brilliant of colours by itself, yet in any mixture it loses that perfection, but still retains a sufficient share of brightness to render it a desirable tint in the purplish gray shadows of the face. Prussian blue, mixed as before-mentioned, makes a bright or dark purple, according as the quantities of either colours are proportioned; but indigo makes still darker, owing to its great natural depth of colour. Smalt and carmine, or lake, form nearly the same tint as ultramarine, and may be used nearly for the same purposes.

Gray. Of gray tints there are various kinds, according to the subjects they are required for. A warm gray tint may be made by duly portioning burnt terra Sienna, Prussian blue, and drop lake; the more terra Sienna in it, the warmer the tint; the more Prussian blue and lake, the colder. Another gray tint, used with success by some eminent miniature painters, was composed of Prussian blue and Chinese vermilion, but on account of the untidy manner with which vermilion incorporates with any other colour, it required a greater proportion of gum than ordinary to make them work or keep together. A third gray tint, which is an excellent one, is formed of drop lake, sap-green, and Prussian blue.

Olive Tints. A very fine olive tint is formed of gail-stone, Nottingham ochre, and carmine, or lake; and another of sap-green and lake simply.

Of Colours proper for Men's Draperies.—We shall, under this head, make some general observations; the first of which is, that in all cloth draperies for men's portraits, it is necessary to add some flake white; as it not only gives the colour the dead appearance which cloth exhibits, but likewise its being incorporated with the flake white, gives it a body which makes the flesh tints appear to more advantage. The next observation is, that in grinding up your draperies, you are to make them appear several degrees lighter in colour than you want them to be when dry—for this reason; the flake white is a colour so very heavy, that, after you float in your coat, it will sink to the bottom, and leave your colours several degrees darker than when it was wet; and finally you are not to be too heavy or thick in floating in your draperies, but merely to see that your colour is evenly spread over the part. Black drapery is formed of lamp black burnt, and flake white; and must be laid in with a good deal of the latter, as otherwise it will be very difficult to manage the shadows so as to produce a pleasing effect. Scarlet is a colour very difficult to lay down rules for making, as in some pictures it is dangerous to make it too bright, for fear of hurting the effect of the face by its brilliancy catching the eye too readily; consequently, if the subject you are painting from life is very pale, you run a very great risk by annexing a very bright scarlet to his picture. We shall therefore only mention that a very bright scarlet is made of Chinese vermilion and carmine, ground together, (without any flake and white;) and

if you want it still rendered brighter when it is dry, fill your pencil with plain carmine, mixed with thin gum-water, and glaze over it nicely; but if, on the contrary, you wish to sadden, or take away a share of its brilliancy, add a little flake white to it, and that will have the desired effect.

List of several of the most eminent Painters of the Old School, with a Scale of their different Merits, so far as regards Composition, Design, Colouring, and Expression.

School.	Name. Date of Birth and Death.	Composition.	Design.	Colouring.	Expression.
Lombard, ...	Albano, born 1578, died 1660,	14	14	10	4
Flemish, ...	Albert Durer, born 1470, died 1528, ..	8	10	10	8
Roman and Florentine, }	Andrea del Sarto, born 1478, died 1530, ..	12	10	9	4
Roman, ...	Barocci, born 1528, died 1612,	14	15	10	10
Venetian, ...	James Bassan, born 1533, died 1613, ..	8	8	17	8

Roman, ...	Vanus, born 1556, died 1634,	13	15	12	13
Roman, ...	Tadec Zaorea, born 1520, died 1556, ..	13	14	10	9

Description of a Rest for the Use of Painters, by Wm. Bruckman, Esq.—The painter's-rest is intended as a substitute for the common maul-stick, the inconvenience of which has been often felt by painters; sometimes from its increasing the pressure, to the fatigue of the hand, which also supports the pallet; often, in spite of the padding with which the end is armed, doing injury to the picture, if not quite dry. These disadvantages are obviated by the following machine; which consists

of a frame, with feet of unequal length, the longest being always placed under the easel, that the pressure of the hand may not turn it over towards the picture. In the outer frame of the rest, a sliding frame is made to rise, and be fixed by a ratchet: if the height required exceed the extent of the ratchet, the swing frame will again extend the elevation, owing to its pivots being placed out of the centre. The machine is capable of any adjustment, from the low sitting elevation of an invalid to a very high standing one, and it is firm enough to steady the hand perfectly.

This figure is a perspective view of the rest; *pp*, two standards, framed together near the foot-board by a cross bar, and by the bar *x* at the top; *q*, a rack, cut in the right-hand one; *r*, the click, catching in it; *s, s*, two other standards, framed together only by the bars *t* and *v*, having rabbets along their outsides, fitting into grooves in the inside of the standards *pp*, which serve as guides to them when sliding up and down. The frame *ss* is supported at any required height by the click *r*; *u u*, a long frame, filling the space between the standards *ss*; it is fixed to these latter by the thumb-screws *ww*. The upper part of this frame forms the rest for the arm; and, in order to prevent it from turning on the screws *ww*, a pin or bolt *x*, pushes in, to fix it: it has a loop-hole, through which a smaller pin passes, to keep it to its place. By withdrawing the little pin *x*, the frame *u u* may be turned round on the screws *ww*, and secured by them and by the bolt, as shown by the dotted lines, to give an additional elevation; the same rack *q* giving the intermediate height between this position and the former. The left-hand figure shews a bird's-eye view of one foot *yy*, and standards *p* and *s*, and part of the frame *u*. The painter gives additional steadiness to the rest, by putting one foot on the foot-board *yy* in front. The whole rest inclines, from top to bottom, about as much as an easel in use generally does, and the long feet go under the canvass, to let it approach near enough.

PAKFONG, or **WHITE COPPER**, a metal composed of copper, nickel, and zinc. The zinc amounts to nearly one half of the whole, and the proportions of copper and nickel are as 5 to 13. This compound metal is much used among the Chinese.

PALÆSTRA, in Grecian Antiquity, a public building, where the youth exercised themselves, in wrestling, running, playing at quoits, &c.

PALAMEDEA, a genus of birds, belonging to the order of *gralla*. The character of this genus is, the bill bends down at the point with a horn, or with a tuft of feathers erect near the base of it: the nostrils are oval; the toes are divided almost to their origin, with a small membrane between the bottoms of each.

PALATE, in Anatomy, the flesh that composes the roof, or the upper and inner part, of the mouth.

PALATINE Counties of England, are Chester, Durham, and Lancaster, the owners of which, the Earl of Chester, the Bishop of Durham, and the Duke of Lancaster, can, or may, or could, pardon treasons, murders, and felonies, appoint their own judges, justices, and issue writs and indictments, as the king can in the other counties that are not palatinate.

PALILICUM, another name for the star *Aldebaran*.

PALING, in Agriculture, a kind of fence-work for fruit trees. It is also a fence made by stakes being driven into the ground.

76.

PALISADES, stakes made of strong split wood, used in fortification, and for the support or defence of embankments.

PALISSE, in Heraldry, a bearing like a range of palisades before a fortification, represented on a fosse, rising up a considerable height and pointed at top, with the field appearing before them.

PALLADIUM. This is a new metal first found by Dr. Wollaston associated with platina, among the grains of which he supposes its ore to exist, or an alloy of it with irridium and osmium, scarcely distinguishable from the crude platina, though it is harder and heavier. Palladium is of a greyish white colour, scarcely distinguishable from platina, and takes a good polish. It is ductile, and very malleable; and being reduced into thin alips, is flexible, but not very elastic. Its fracture is fibrous and in diverging striz, shewing a kind of crystalline arrangement. In hardness it is superior to wrought iron. Its specific gravity is from 10.9 to 11.8.

PALLADIUM, a statue of Minerva, which the Trojans imagined fell from heaven, and that their city could not be taken whilst that remained in it.

PALLAS, one of the new planets discovered by Dr. Olbers, March 28, 1802. It is situated between the orbits of Mars and Jupiter, and is nearly of the same magnitude with Ceres, but of a less ruddy colour. It is surrounded with a nebulosity of less extent, and performs its annual revolution in nearly the same period. The planet Pallas, however, is distinguished in a very remarkable manner from Ceres and all other primary planets, by the immense inclination of its orbit. While these bodies are revolving round the sun in almost circular paths, rising only a few degrees above the plane of the ecliptic, Pallas ascends above this plane at an angle of about thirty-five degs., which is nearly five times greater than the inclination of Mercury. From the eccentricity of Pallas being greater than that of Ceres, or from a difference of position in the line of their apsides, while their mean distances are nearly equal, the orbits of these two planets mutually intersect each other; a phenomenon which is altogether anomalous in the solar system.

PALLET, among Painters, a little oval table or picco of wood, or ivory, very thin and smooth; on and round which the painters place the several colours they have occasion for, to be ready for the pencil. The middle serves to mix the colours on, and to make the tints required in the work. It has no handle, but instead thereof a hole at one end to put the thumb through to hold it.

PALLET, among Potters, crucible makers, &c., a wooden instrument, almost the only one they use for forming, beating, and rounding their works: they have several kinds; the largest are oval, with a handle; others are round, or hollowed triangularly; others, in fine, are in manner of large knives, serving to cut off whatever is superfluous on the moulds of their work.

PALLET, in Gilding, an instrument made of a squirrel's tail, to take up the gold leaves from the pillow, and to apply and extend them on the matter to be gilt.

PALLIUM, or **PALL**, an archiepiscopal vestment of white woollen cloth, about the breadth of a border, made round, and thrown over the shoulders: upon this border there are two others of the same matter and form, one of which falls down upon the breast and the other upon the back, each having a red cross upon it; several crosses of the same colour being likewise upon the upper part of it about the shoulders. The pall was part of the imperial habit, and originally granted by the emperors to patriarchs, but at present it is given by the pope as a mark of the apostolic power, without which neither the function nor title of archbishop can be assumed by the bishops of his communion.

PALM, an ancient long measure taken from the extent of the hand. The Roman palm was of two kinds; the great palm, taken from the length of the hand, answered to our span, and contained twelve digits, or fingers' breadths, or nine Roman inches, equal to about eight and a half English inches. The small palm, from the breadth of the hand, contained four digits or fingers, equal to about three English inches. The Greek palm, or *doron*, was also of two kinds; the small contained four fingers, equal to little more than three inches; the great palm contained five fingers. The Greek double palm, called

9 H

dichas, contained also in proportion. The modern palm is different in different places, where it is used. It contains

PALMÆ, *Palms*, comprehend several genera of plants, with simple stems, which at their summits bear leaves resembling those of ferns, being a composition of leaf and branch.

PANACEA, among Physicians, denotes an universal medicine, or a remedy for all diseases.

PANAX, (*Gin-Seng*), a genus of plants belonging to the polygamia class, of which there are nine species.

PANCREATIC JUICE, a liquid secreted by the pancreas, which is found to be analogous to saliva, and probably serves the same purpose in promoting the digestion of the food.

PANDECTS, or **PANDECTÆ**, in Jurisprudence, are 50 books of Roman civil law, abridged by Justinian's order; though Papias extends the signification of this word to the books of the Old and New Testament. The original copy (supposed to be) is in the possession of the Medici family at Florence. The pandects of Justinian sufficiently shew how zealously the lawyers and advocates of passive obedience laboured in the cause of prerogative.

PANEL, a schedule or roll of such jurors as the sheriff returns to pass upon any trial; and impanelling a jury, is returning their names in such schedule of parchment. In Scots law, the prisoner at the bar is the panel.

PANEL, in Joinery, is a tympanum, or square piece of thin wood, sometimes carved, framed or grooved in a larger piece between two upright pieces and two cross pieces.

PANIC, denotes an ill-grounded terror or fright. The origin of the phrase is from Pan, one of the captains of Bacchus, who with a few men put a numerous army to rout, by a noise which his soldiers raised in a rocky valley favoured with a great number of echos: for this stratagem making their numbers appear much greater than it really was, the enemy quitted a very commodious encampment, and fled. Hence, all ill-grounded fears, have been called panics, or panic fears.

PANICUM, a genus of plants belonging to the triandria class.

PANICUM Miliaceum. *Millet*.—Millet is of two kinds, the brown and yellow. They are sometimes sown in this country for feeding poultry, and also for dressing; i. e. it is divested of the husk by being passed through a mill, when it is equal to rice for the use of the pastry cook. The seed used is from one to two bushels per acre. This is very commonly grown in Italy, and on the shores of the Mediterranean sea, from which large quantities are annually exported to the more northern countries.

PANTHER. See **FELIS**.

PAPAYER, the *Poppy*, a genus of the monogynia order, in the polyandria class of plants; and in the natural method ranking under the 27th order, *rhœadæ*. The corolla is tetrapetalous, the calyx diphyllous, the capsule bilocular, opening at the pores below a persisting stigma. There are nine species: 1. The *somniferum*, or somniferous common garden poppy. There are of this a great many varieties, some of them extremely beautiful. The white officinal poppy is one of the varieties of this sort. It grows often to the height of five or six feet, having large flowers both single and double, succeeded by capsules or heads as large as oranges, each containing about 8000 seeds.

PAPER, **WRITING**, is, in Europe, manufactured from linen rags chiefly. These rags are first cut or chopped, then dusted, and reduced to pulp in mills, by cylinders, &c. The workman now immerses into the pulp vat a mould composed of wire cloth, and furnished with a frame to retain the stuff. He then draws out as much of this pulp as is necessary for one sheet, over which he places a felt, to absorb the moisture; and thus a felt and sheet of paper are placed alternately, till he has formed six quires of paper. When the last sheet is covered with felt, the whole is pressed, and the sheets are suspended on cords to dry. The next operation is sizing, which is performed by

plunging the paper into a vessel of size, containing a small portion of alum. The paper is then dried, and folded into quires of 24 sheets, and finally made up into reams containing 20 quires each.

Blotting paper, drawing, engraving, and printing paper, are prepared much in the same way, but they are not so highly sized. In lieu of rags, barley straw is employed in the manufacture of paper, but it will only serve for common purposes, as it communicates an unpleasant tinge.

To make Stained Paper. This is done by applying, by soft brushes, any of the colours used for tinging other substances, after tempering them properly with size or gum water. If the paper is to be of a uniform colour, it must be fixed by several thin coatings, each being suffered to dry before another is applied; otherwise the shade will appear clouded.

Marbled Paper, is a sort of paper variously stained, or painted as it were with divers colours; made by applying a sheet on the surface of a liquor, wherein colours, diluted with oil or ox's gall, are suspended. The manner of making it is thus:—A trough is provided of the shape and dimensions of a sheet of the paper to be marbled, and about four fingers deep; this is made of lead or wood well joined, and pitched or primed to contain the liquor. For the liquor, a quarter of a pound of gum tragacanth is macerated four or five days in fair water; this they stir from time to time, and add to it daily fresh water, till it be of a consistency somewhat thinner than oil; then they strain it into the trough. The colours to be applied thereon, for blue, are, indigo ground up with white lead, or Prussian blue and verditer may be used; for green, indigo and orpiment, the one ground and the other tempered, mixed and boiled together with common water; or verdigris, a mixture of Dutch pink and Prussian blue, or verditer, in different proportions: for yellow, orpiment bruised and tempered; or Dutch pink and yellow ochre: for red, the finest lake, ground with raspings of Brasil wood, which has been prepared by boiling half a day; or carmine, rose pink, vermilion, and red lead; the two latter of which should be mixed with rose pink or lake, to bring them to a softer cast: for orange, orange lake, or a mixture of vermilion, or red lead, with Dutch pink: for purple, rose pink and Prussian blue. Into all these colours, properly ground with spirit of wine, they put a little ox or fish gall, which is two or three days old; and if the colours dilute not of themselves sufficiently, they add more gall; on the contrary, if they spread too much, the gall is over-dosed, and must be corrected by adding more of the colour without gall.

For the operation of marbling, when the gum is well settled in the trough, they extend a sheet of paper, and plunge it very shallow into the liquor, suddenly lifting it out again, in order to stir up and raise the subsiding gum towards the surface, and for the more universal impregnating of the liquor. This done, and all the colours ranged in gallipots on the table, where also the trough is placed, they begin by dipping a brush of hog's hair into any colour, commonly the blue first, and sprinkle it on the surface of the liquor: if the colour has been rightly prepared, it will dilate itself duly therein. This done, the red is applied in the like manner, but with another pencil; after this, the yellow; lastly, the green. For white, it is made by only sprinkling fair water, mixed with ox's gall, over the liquor. When all colours are thus floating on the liquor, to give them that agreeable cambletting, which we admire in marble paper, they use a pointed stick; which being applied by drawing it from one side of the trough to the other, with address, stirs up the liquor and fluctuating colours; then with a comb, made of wood, about five inches long, with brass teeth, about two inches in length, and a quarter of an inch distant from each other, taken by the head with both hands, they comb the surface of the liquor in the trough, from one extreme to another, permitting only the teeth to enter; this being performed with a gentle and uniform motion, makes those clouds and undulations on which the beauty of the paper depends. If it be further desired to have the colours lie in any other fantastical posture, representing serpents, or the like, it is effected with the pointed stick above mentioned, by drawing it over what has been already combed; but this must be done with a dexterous hand, and with a shallow dip into the liquor, circling, as if you would draw some flourish, or figured letter. Lastly, the

colours being in this posture, the operator displays and applies on them a sheet of white moistened paper; to do which, artist-like, requires a sleight only to be obtained by practice; because the surfaces of the liquor and the paper are to meet equally in all parts; which done, before the colours have time to soak through, which, unless the paper be very thick, will be in the space of two or three pulses, he lifts up the paper nimbly, and with an even hand; and then, after spreading it a while on a board, hangs it on a line to dry; which, when sufficiently done, they first rub it with a little soap, and then polish it with a marble stone, ivory knob, or glass polishers; or with a burnisher of jasper or agate. It must be observed, that the sprinkling of the colours is to be renewed, and all the other ceremonies performed with the stick and comb, at every application of fresh paper, by reason that every paper takes off all the colour from the liquor.

Rice Paper, is a curious sort of paper, made by the Chinese; it is semi-transparent, of a firm texture, and feels somewhat like the article manufactured from the *papyrus*. The Chinese also make paper from the rind or bark of the mulberry tree, the elm, the hamboo, and cotton tree. In fact, every different province has its own provincial paper. The second skin of the bamboo bark is peculiarly soft and white. This they beat in fair water into a pulp, which they take up in large moulds, so that some sheets are above twelve feet in length. They are completed by dipping them in alum water, which serves in place of our size. Each province not only manufactures a paper peculiar to itself, but stains it pink, green, or straw colour, as their fathers from time immemorial have done.

Ivory Paper. The properties which render ivory so desirable a subject for the miniature painter, and other artists, are, the evenness and fineness of its grain, its allowing all water colours laid on its surface to be washed out with a soft wet brush, and the facility with which the artist may scrape off the colour from any particular part, by the point of a knife, or other convenient instrument, and thus heighten and add brilliancy to the lights in his painting more expeditiously and efficaciously than can be done in any other way. The high price of ivory, the impossibility of obtaining plates exceeding very moderate dimensions, and the coarseness of grain in the larger of these, and its liability, when thin, to warp by changes of the weather, together with its property of turning yellow by long exposure to the light, owing to the oil which it contains, render some substitute very desirable. The ivory paper we are now about to describe, admits of traces being made on the surface by a hard black lead pencil, which are much easier effaced by Indian rubber than from common drawing paper; and this circumstance, with the extremely fine lines which its hard and even surface is capable of receiving, peculiarly adapts it for the reception of the most delicate pencil drawings and outlines. The colours laid upon it have a greater brilliancy than when laid upon ivory, owing to the superior whiteness of the ground. The following is the process given by Mr. Einslie, of Stratton Ground, Westminster, to the Society of Arts, for which he was voted the sum of thirty guineas:—Take a quarter of a pound of clean parchment cuttings, and put them into a two-quart pan, with nearly as much water as it will hold; boil the mixture gently for four or five hours, adding water from time to time, to supply the place of that driven off by evaporation; then carefully strain the liquor from the dregs through a cloth, and when cold it will form a strong jelly, which may be called size No. 1. Return the dregs of the preceding process into the pan, fill it with water, and again boil it as before for four or five hours; then strain off the liquor, and call it size No. 2. Take three sheets of drawing paper, (outsides will answer the purpose perfectly well, and being much cheaper, are therefore to be preferred,) wet them on both sides with a soft sponge dipped in water, and paste them together with the size No. 2. While they are still wet, lay them on a table, and place them upon a smooth slab of writing slate, of a size somewhat smaller than the paper. Turn up the edges of the paper, and paste them on the back of the slate, and then allow the paper to dry gradually. Wet, as before, three more sheets of the same kind of paper, and paste them on the others, one at a time; cut off with a knife what projects beyond the edges of the slate, and when the whole has become perfectly dry, wrap a

small piece of slate in coarse sand paper, and with this rubber make the surface of the paper quite even and smooth. Then paste on an inside sheet, which must be quite free from spots or dirt of any kind; cut off the projecting edges as before, and when dry, rub it with fine glass paper, which will produce a perfectly smooth surface. Now, take half a pint of the size No. 1, melt it by a gentle heat, and then stir it into three table-spoons full of fine plaster of Paris; when the mixture is completed, pour it out on the paper, and with a soft wet sponge distribute it as evenly as possible over the surface. Then allow the surface to dry slowly, and rub it again with fine glass paper. Lastly, take a few spoons full of the size No. 1, and mix it with three-fourths its quantity of water; unite the two by a gentle heat, and when the mass has cooled, so as to be in a semi-gelatinous state, pour about one-third of it on the surface of the paper, and spread it evenly with the sponge; when this has dried, pour on another portion, and afterwards the remainder; when the whole has again become dry, rub it over lightly with fine glass paper, and the process is completed; it may, accordingly, be cut away from the slab of slate, and is ready for use.—The quantity of ingredients abovementioned is sufficient for a piece of paper 17½ by 15½ inches. Plaster of Paris gives a perfectly white surface; oxide of zinc, mixed with plaster of Paris, in the proportion of four parts of the former to three of the latter, gives a tint very near resembling ivory; precipitated carbonate of barytes gives a tint intermediate between the two.

The method of making *Whity Brown Paper* is the following; The constituent material consists in old worn-out sacks, which are first chopped into small pieces by a labourer, who is for that purpose furnished with a sharp chopper and a block; the fragments thus prepared are well washed by agitating them in a vat of water, changed as often as needful; after this they are cast into the mill, which consists of a longitudinally denticulated cylinder, or roller, not much unlike the crimping roller used by a laundress for crimping frills, &c.; this roller having a motion given it by a water wheel, revolves on its axis with great velocity, within the fixed concave section of a cylinder, likewise denticulated, and fitted so closely to it, but without contact, as to grind the shreds of sacking, which are now mixed with water to a fine pulp, as they are drawn in between the two surfaces. This part of the apparatus is contained in one side or division of a trough, of an oblong curved form, with a partition in the middle, leaving it open at each end, thus forming a continuous canal in which the fluid moves round, the current which passes through the grinders being occasioned by the rapid revolution of the indented roller in the liquid. When the fibres have thus acquired a proper state of separation, the pulp is suffered to run out of the mill trough into a large receptacle, to await the next process. A sufficient portion is now transferred into another vat, where it is further diluted with water to a proper consistence, and moderately warmed by steam, circulated in pipes at the bottom of the vessel, and to prevent the pulp precipitating, the whole is kept in constant motion by an apparatus somewhat like a reel, revolving within at the lower part, and put in action also by a small water wheel. In this state, the colour, the consistency, and the ebullition, cause it to bear a striking resemblance to a huge mass of water gruel, "thick and slab." At this vessel stands a man furnished with a frame of wirework, very similar to what is used for meat safes, but of a closer texture, and not much unlike a four-sided shallow sieve, and of the size and form of the sheet of paper to be made; this he dips into the liquid, and on lifting it out the water drains through the wirework, and the frame is covered with a thin layer of the pulp; the frame is then inverted on a piece of flannel, when the pulp quits the frame, and lying on the flannel, resembles, and is in fact become, a sheet of wet paper: another flannel is laid on this for the next sheet, and so alternately, until the pile has accumulated to a certain quantity, when the whole is put into a powerful press, by which the water held in the material is expressed, and the paper thus brought to a state of comparative dryness. Each sheet is now taken from between the flannels, and hung across laths in the drying rooms: when dry, is made up into quires, again pressed, and packed up in reams for the consumer.

PAPER Office, an office in which all the public writings, mat-

ters of state and council, proclamations, letters, intelligences, negotiations abroad, and generally all despatches that pass through the office of the secretaries of state, are lodged by way of library.

PAPIER MACHE, is a substance made of cuttings of white or brown paper, boiled in water, and beaten in a mortar till they are reduced into a kind of paste; and then boiled with a solution of gum arabic, or of size, to give tenacity to the paste, which is afterwards formed into different toys, &c. by pressing it into oiled moulds. When dry, it is covered with a mixture of size and lamp black, and afterwards varnished.

PAPISTS, persons professing the popish religion. By several statutes, if any English priest of the church of Rome, born in the dominions of the crown of England, come to England from beyond the seas, or tarried in England three days, without conforming to the church, he was guilty of high treason; and they also incurred the guilt of high treason who were reconciled to the see of Rome, or procured others to be reconciled to it. By these laws also, papists were disabled from giving their children any education in their own religion. If they educated their children at home, for maintaining the schoolmaster, if he did not repair to church, or was not allowed by the bishop of the diocese, they were liable to forfeit 10*l.* a month, and the schoolmaster was liable to the forfeiture of 40*s.* a day; if they sent their children for education abroad, they were liable to a forfeiture of 100*l.* and the children so sent were incapable of inheriting, purchasing, or enjoying any lands, profits, goods, debts, legacies, or sums of money: saying mass was punishable by forfeiture of 200 marks; and bearing it, by a forfeiture of 100*l.* But during the late reign the Roman Catholics have been in some measure relieved from many of the odious and unjust restrictions formerly imposed on them. See 18. Geo. III. c. 60; and 31 Geo. III. c. 22. Yet as the statute 1 William and Mary, st. 1, c. 18, called the Toleration Act, does not apply to Catholics, nor to persons denying the Trinity, they cannot serve in corporations, and are liable to the test and corporation act. They cannot sit in the house of commons, nor vote at elections, without taking the oath of supremacy, and cannot present to advowsons, although Jews and Quakers may. But the person is only disabled from presenting, and still continues patron. It seems they may serve on juries; but Catholic ministers are exempted. They also are entitled to attend the British factories and their meetings abroad, and may hold offices to be wholly exercised abroad, and may also serve under the East India Company. They are also enabled to hold any rank in the army, having been excused by a late statute from the oaths formerly required. In Ireland, papists may be justices of the peace, and are qualified to serve in corporations; but party spirit much prevailing, they are seldom elected.

PAPYRUS, a famous reed, or species of dog grass, from which was made the celebrated paper of Egypt.

PAR, in Commerce, signifies any two things equal in value.

PARABOLA, is one of the conic sections formed by the intersection of a plane and a cone, when the plane passes parallel to the side of the cone. This figure, like all other conic sections, may be treated of in three different ways, viz. 1. As being produced by the intersection of a plane and cone. 2. According to its description in plano. And, 3. As being generated by the motion of a variable line or ordinate, along another fixed line or directrix; in which case the properties of the curve are deduced from the equation by which it is defined or expressed. The vertex of a parabola is the point in which the cutting plane meets the side of the cone. Thus, *V* is the vertex of the parabola *m V o*. The axis is a straight line, *V n*, drawn from the vertex *V*, so as to divide the figure into two equal parts; and any line parallel to the axis is called a diameter. If a straight line, terminated by the curve, be bisected by the axis or by a diameter, it is called a double ordinate to the axis, or to that diameter, respectively; and its half is called an

ordinate to it. The axis cuts its ordinates at right angles. Thus *M N O* is a double ordinate, and *M N* an ordinate to the axis *V n*. The segment of the axis, or of a diameter, between its vertex and ordinate, is called an abscissa of the axis, or of that diameter. Thus *V N* is an abscissa of the axis. A third proportional to the abscissa, and its corresponding ordinate, is called the parameter, or latus rectum. The focus is that point in the axis where the abscissa is equal to one-fourth of the parameter to the axis. The double ordinate, drawn through the focus, is called the parameter to the axis, or the principal latus rectum.

PARACENTRIC MOTION, is the motion of a planet towards the centre of attraction, or the sun. The orbits of the planets being elliptical, they are sometimes nearer, and sometimes more remote, from the sun; and the difference in this distance is what is called the paracentric motion.

PARADE, in War, is a place where the troops meet to go upon guard, or any other service. In a garrison, where there are two, three, or more regiments, each have their parade appointed, where they are to meet upon all occasions, especially upon any alarm. And in a camp, all parties, convoys, and detachments, have a parading place appointed them at the head of some regiment.

PARADISBA, bird of Paradise; in Natural History, a genus of birds of the order *Picæ*, and they chiefly inhabit North Guinea, from which they migrate in the dry season into the neighbouring islands. They pass in flights of thirty or forty, headed by one whose flight is higher than that of the rest. They are often distressed by means of their long feathers, in sudden shifts of the wind, and unable to proceed in their flight are easily taken by the natives, who also catch them with birdlime, and shoot them with blunted arrows. They are sold at Amoy for an iron nail each, and at Banda for half a rix dollar. Their food is not ascertained, and they cannot be kept alive in confinement. The smallest bird of paradise is supposed by Latham to be a mere variety of the above. It is found only in the Papuan islands, where it is caught by the natives often by the head, and exenterated, and seared with a hot iron in the inside, and then put into the hollow of a bamboo, to secure its plumage from injury.

PARADOX, in Philosophy, a proposition seemingly absurd, as being contrary to some received opinion; but yet true in fact.

PARAGRAPHINE. A new invention, whose object is to avert hail storms, as the electrical conductors serve to obviate danger from lightning. In this climate, the hail is seldom so violent as to occasion any very serious losses; but in many parts of the continent, it is dreaded as the most destructive enemy of the husbandman; and we have known insurance companies established for the sole purpose of guarding against loss by hail-storms. The inventor of the Paragrandine is a Signor Apostolla. One of the latest accounts of its beneficial effects, published by Signior Antonio Perotti of San Giovanni di Cassara, states, that having on a piece of land belonging to himself, containing 10,000 perches in extent, fixed up several of the Paragrandini, he had the satisfaction to find that no injury was done by hail to the corn, and very little to the vines, although no less than fourteen storms had occurred in the current year, five of which appeared to threaten great mischief to his fields, but passed over them, and fell on the neighbouring lands of Valvasoni, Baguarola, and Savorgnano. These instruments are composed of metallic points and straw ropes, bound together with hempen or flaxen threads. Dr. Astolfi, in a letter to professor Francesco Orioli of Bologna, relates, that a hail storm proceeding in a direction from Bentivoglio to S. Giovanni Triano, came near the lands of Count Casoni, which were protected by Paragrandini; on approaching which the clouds were seen at once to disperse. A notice, contained in an official report to the Milan government by the Gonfaloniere of San Pietro in Casale, states, that during a stormy day, when there were many claps of thunder and flashes of lightning, he went out to observe the effects of the Paragrandine, and noticed the electric fluid to be attracted by the points of the straw in the machine, around which the flame played in graceful curves; while in the adjoining fields not protected by the Paragrandine, much ruin fell, and the lightning did considerable mischief.

PARAGUAY TEA. A modern writer, giving a description of the province of Buenos Ayres, (the population of which he estimates at 1,100,000,) says, the Paraguay tea is an article of the greatest importance all over that part of the continent. It is a plant which rises about $1\frac{1}{2}$ feet high, with slender branches and leaves, something like those of senna. The herb is in general and almost universal use. It is infused, and made nearly the same way as China tea, excepting that the branches are put in along with the leaves, and that it is drunk out of the vessel that it is made in, through a silver and glass pipe, as soon as possible. The smell and colour of this drink is said to be equal to the Chinese teas. None of this tea had, in 1826, reached England, so that its merits must be taken on report. As our commerce, however, increases with the South American countries, some of this herb will naturally find its way into Britain, and if it should prove acceptable to the general taste, and become a rival to the China tea, it would be an important staple in the commerce of the two countries.

PARALLATIC ANGLE, is the angle subtended by two lines drawn from the centre of a planet, the one to the centre of the earth, and the other to the same point on its surface. See PARALLAX.

PARALLAX, in Astronomy, an arc of the heavens intercepted between the true and apparent place of any of the heavenly bodies; that is, between its place as viewed from the centre of the earth, and from some point on its surface. Thus, let ABC be the earth, C its centre, v, v', v'' three different planets, or three different positions of the same planet; then its true places in these positions, as seen from the centre C, and as referred to the heavens, will be V, V', V'' ; but their apparent places will be w, w', w'' , and the arcs $vV, v'V',$ and $v''V''$, will be the measures of the parallaxes, or of the parallactic angles $Vvw, V'w',$ &c. or of $DvC, Dv'C,$ &c. to which they are equal.

The **Horizontal PARALLAX**, or that which has place when the star is in the horizon, is the greatest; the angles and arcs both diminish from the horizon to the zenith, where it becomes nothing, as is obvious from the above figure. Whence it is obvious, that the parallax diminishes the apparent altitude of a body; but that this diminution is less and less, as the altitude becomes greater and greater; and it has, therefore, a contrary effect to refraction, which always increases the apparent height of any of the celestial objects. Parallax receives particular denominations, according to the circle upon which it is computed.

PARALLAX of Altitude, is the difference between the true and apparent altitude of a planet, as above described.

PARALLAX of Right Ascension and Declension, is an arch of the equinoctial, by which the parallax of altitude increases the ascension and diminishes the descension.

PARALLAX of Declination, is an arch of a circle of declination, by which the parallax of the altitude increases or diminishes the declination of a star.

PARALLAX of Latitude, is an arch of a circle of latitude, by which the parallax of altitude increases or diminishes the latitude.

Menstrual PARALLAX of the Sun, is an angle formed by two right lines; one drawn from the earth to the sun, and another drawn from the sun to the moon, at either of their quadratures.

PARALLAX of the Annual Orbit of the Earth, is the difference between the heliocentric and geocentric place of a planet, or the angle at any planet subtended by the distance between the earth and sun.

PARALLAX of the Planets. The exact determination of the parallax of the planets is of the greatest importance in astronomy, as it is from that, or indeed from the parallax of any one of them, we estimate their several distances. For if the parallax, or the angle which is subtended by the terrestrial radius, at any planet be known, its distance from the earth is also known; whence its distance from the sun, as also the distances of all the other planets, will be known also, from the third law of Kepler, viz. that the squares of the periodic times are as the

cubes of the distances. To illustrate this it may be observed, that in very small angles, as are those of the parallaxes, and while the side subtending those angles remains constant, the angles will be reciprocally as the distances; that is, if DC be very small with regard to CV, then the angle DVC : angle

$DMC :: CV : CM$ nearly. For in this case we may consider $DV = CV$ and $DM = CM$, also DC will not differ sensibly from the arc of

the circles which subtends the angles at V and M, and therefore putting $3.1416 = p$ we have $\frac{DC}{2p \times CV}$ for the measure of

the angles DVC, and $\frac{DC}{2p \times CM}$ for the measure of the angle

DMC, which are therefore reciprocally as CV and CM. It is obvious, therefore, that the parallax of any one of the planets being found, that of all the others may be determined, because their proportional distances from the sun are accurately known from Kepler's law, above mentioned. There are many different methods of determining the parallax of the planets; but being an extremely delicate operation, on account of the smallness of the angles, we had several different results; till the parallax of Venus was determined by means of her transits over the sun's disc, in 1761 and 1769; and as it is on this, that a great part of our knowledge depends respecting the absolute distances of the planets from the sun, it will be proper to give a sketch of the principles on which it rests, without, however, attempting to enter into the minutiae of the observations and calculations. Let V, V' represent the orbit of Venus, and E, E' that of the earth; V and E being the positions of these two

bodies at the true time of Venus entering upon the disc of the sun, that is, to an observer situated at the earth's centre, by whom her place in the heavens would be referred to v , which would be also the place of the eastern limb of the sun. But to an observer situated at A, Venus would be referred in the heavens to w , and the eastern limb of the sun to s ; and consequently, to such an observer, Venus, instead of appearing on the sun's disc, would be distant from him by the arc SW , that is, by an arc equivalent to the difference of the parallax of Venus and of the sun. And in the same manner, supposing the earth, during the transit, to have moved in its orbit from E to E' , and Venus from V to V' ; it is obvious, from what is said above, that at the time when this planet was just quitting the sun's western limb, to an observer situated at the centre E, would be referred by an observer at A to v' , and the western limb of the sun at s' ; so that, in the first case, she would not enter the sun's disc till after the true time, and in the latter, she will appear to leave the sun's disc before the true time; and as in some parts of the world, in the transit above alluded to, Venus was seen both to enter and emerge from the sun's limb by the same observer, the whole difference between the true and apparent time of the transit became known, and half this difference was the time Venus was in passing over the arc ws ; whence the measure of that arc became known, or, which is the same, the difference between the parallax of Venus and that of the sun. But to those observers who could not see both the immersion and emersion, the difference between the true and apparent time of either, when converted into seconds of a degree, was what determined the difference of the parallax of the two bodies. Now this difference being known, as

also the proportional distances of the Earth, Venus, and the Sun, their absolute parallaxes were determined, this, as we have shewn above, being reciprocally as the distances. Let $m : n$ represent the ratio of the distance Ev to ES , also P and p the parallaxes of Venus and the Sun, which are required, and $P - p = q$, the difference of their parallaxes as found above; then, $n : m :: P : p$, whence $n - m : m :: P - p = q : \frac{m}{n - m} = p$, the sun's parallax. In this manner, aided by subsequent observations, &c. Laplace has determined the parallax of the sun to be $8''\frac{1}{2}$, whence its distance is found to be about 94 million miles. And hence the parallaxes of the several planets are determined as follows:—Greatest horizontal parallax of the Sun, $8''.75$; Mercury, $14''.58$; Venus, $29''.16$; Mars, $17''.50$; Jupiter, $2''.08$; Saturn $1''.027$; Uranus, $0''.415$.

PARALLAX of the Moon. This is much more considerable than in any other of the heavenly bodies, on account of its proximity to the earth, and is much easier determined than any of the others; one of the most simple and correct methods being as follows:—Observe the moon's meridian altitude with the greatest accuracy, and mark the moment of observation: this time being equated, compute her true longitude and latitude, and from these find her declination; and from her declination, and the elevation of the equator, find her true meridian altitude; if the observed altitude be not meridian, reduce it to the true time for the time of observation; take the refraction from the observed altitude, and subtract the remainder from the true altitude, and the remainder is the moon's parallax: by this means the parallax of the moon has been found as follows, viz. Greatest parallax, $61' 32''$. Least parallax, $54' 4''$. Mean parallax, $57' 48''$. But Laplace makes her mean parallax $56' 34''.2$.

PARALLAX of the Fixed Stars. As the distances of the heavenly bodies are determined by means of their parallaxes, every possible method has been attempted to ascertain the parallax of some of the fixed stars, but their distance is so immense, that not only have they no parallax, as compared with the terrestrial radius, but even the whole diameter of the earth's orbit, though near 200 million miles, is not sufficient to render any difference in their apparent places at all evident, which, if it only amounted to one second, would be discoverable by modern instruments. This distance, therefore, great as it is, is not more than a mere point compared with the distance of the nearest of the fixed stars.

PARALLEL MOTION, is a term used among practical mechanics to denote the rectilinear motion of a piston rod, &c. in the direction of its length; and contrivances by which such alternate rectilinear motions are converted into rotatory ones, and *vice versa*, in pumps, steam-engines, saw-mills, &c. are usually called contrivances for parallel motions. In motions of this kind it is generally thought a desirable thing to give the piston rod, the saw, or the like, a uniform velocity through the whole of its progress; then to bring it at once to rest, again to give it instantaneously a finite velocity in the opposite direction, and so on. But this seems impossible in nature; all changes of motion which we observe are gradual, because all impelling bodies have some elasticity or softness by which they yield to compression; and, in the way in which pistons are commonly moved, viz. by cranks, or something analogous to them, the motion is very sensibly gradual. Hence, it may be observed, that most attempts to correct these inequalities in motion are misplaced; and if they could be accomplished, would greatly injure the pump or other machine. One of the best methods of producing this effect is, to make the piston rod consist of two parallel bars, having teeth in the sides which front each other. Let a toothed wheel be placed between them, having only the half of its circumference furnished with teeth. It is evident, without any further description, that if this wheel be turned uniformly round its axis, the piston rod will be moved uniformly up and down without intermission. This has often been put in practice, and the piston rod made to work between grooved rollers; but the machine always went by jolts, and seldom lasted a few days. Unskilled mechanists attributed this to defect in the execution; but the fault is essential, and lies in the principle. The machine

could not perform one stroke if the first mover did not slacken a little, or the different parts of the machine did not yield by bending, or by compression; and no strength of materials could withstand the violence of the strains at every reciprocation of the motion. This is chiefly experienced in great works which are put in motion by a water wheel, or some other equal power exerted on the mass of matter of which the machine consists. The water wheel being of great weight, moves with considerable steadiness or uniformity; and when an additional resistance is opposed to it by the beginning of a new stroke of the piston, its great quantity of motion is but little effected by this addition, and it proceeds very little retarded; and the machine must either yield a little by bending and compression, or go to pieces, which is the common event. Cranks are free from this inconvenience, because they accelerate the piston gradually, and bring it gradually to rest, while the water wheel moves round with almost perfect uniformity. The only inconvenience (and it may be considerable) attending this slow motion of a piston at the beginning of its stroke is, that the valves do not shut with rapidity, so that some water gets back through them. But when they are properly formed and loaded, this is but trifling. It would seem, then, that those contrivances in which the piston rod communicates the rotatory motion by means of a crank, or something similar in its effect, are most fit to be adopted in practice; and that the attempts of mechanists in this point of view may, in all probability, be properly restrained to the methods of keeping the piston rod, &c. from deviating to any side, during its alternate motion. Two or three of the best methods of performing this, with which we are acquainted, are the following:—

1. Let a fixed circular ring, whose diameter is equal to the stroke of the piston, have teeth all round the interior parts of its circumference; and let a smaller wheel, whose diameter is only half that of the ring, have equal teeth on the exterior part of its rim, to play into the teeth of the ring; let the axis of the wheel, to which the rotatory motion is to be communicated, pass through the centre of the larger ring; and let a moveable bar join the centre of this ring to that of the smaller wheel. Then, if the upper extremity of the piston rod be attached to a pin fixed on the rim of the inner wheel, at the place where the two wheels are in contact in their lowest point, and the rod be put into motion, it will cause the small wheel to revolve upon the inner part of the fixed ring, and by this means give the proposed rotatory motion to the axis passing through the centre of the ring. At the same time, the extremity of the piston rod will be confined to move in the vertical diameter of the ring; because it is made to describe an epicycloid of that kind, which is formed by a circle rolling along the inside of another circle of double diameter; in which case, it is well known, the epicycloid becomes a diameter of the larger circle, and the smaller circle makes two complete revolutions, while it is moving from any one point of the larger circle to the same point again. This contrivance was devised, we believe, by Mr. White, an Anglo-American. It is almost unnecessary to observe, that the converse is equally applicable in the conversion of a rotatory into a parallel motion.

2. Another method is represented in fig. 2, where the piston rod is kept from deviation. A is the cylinder, B the piston, C the piston rod, D the crank, and E the connecting rod of the crank and piston rod. When the piston is at e , the crank is at a ; when the piston is at B, the crank is either at g or b ; and when the piston is at g , the crank is at f ; so that when the motion of the crank is uniform, that of the piston is variable. The rod H, equal in length to the crank D, moves about the centre F, and is joined to one end of the rod I; to the other end of which is connected the socket L, that receives the top end of the piston rod. A certain point m is taken at pleasure in the rod I, to carry a short axle for the rods K, which are broken in the figure to shew the socket L. To find the centre of motion of the rods K, move the end L of the rod I up and down in the vertical line cfa , and mark three positions α, m, r , of the point m on that rod; describe a circle to pass through those three points; its radius will be equal to the length of the rods K, and its centre will be the point where those rods must be fixed to a bolt or axle in the framing. This contrivance causes the top of the piston rod to move from P by L to O, and back

again by L to p ; and the dotted lines show the position of the several rods at the extremities of the motion. In fig. 3, we have given a horizontal section, to show the connexion of H , I , K , &c. pointing out in what way I grasps L , and E both. The inequality of the piston's motion will be reduced by making the connecting rod E as long as circumstances will permit. If the rod I were extended to the left of the point p , the same kind of apparatus would become a lever with a moveable fulcrum, by means of which a weight might be raised in a vertical line from P to O ; or a pump piston rod worked without deviation.

This construction is described in a prismatic form, by Professor Playfair, in his *Outlines of Nat. Philosophy*, vol. 1. art. 365.

3. A third method is exhibited in fig. 1, where are three rods A , B , and C , besides the connecting rod D . The rods A and C are of equal lengths, and the connecting rod is attached to the middle point of the rod B . The guides A , and C , are fixed at their ends E and F , by bolts to the framing. Thus the point B , to which is fixed the top of the piston rod, is made to move in the right line bBb' ; and the dotted lines show the positions of the rods at the extremities of the stroke. This method, and the preceding, were devised by Mr. William Dryden, a mechanic whose ingenuity needs not our encomium.

4. Another method is shewn in fig. 4. A and B are two bolts in the framing at equal distances on opposite sides of the vertical line in which the piston is to move. AC , BD , two bars of equal length, each equal to about half the distance AB .

CL , DL , two other equal bars, rather more than double the length of the former, moving freely on joints at C and D . At L is a socket, as in figure 2, to receive the top of the piston rod, and to which the bars CL , DL , and the connecting rod E , are attached. By this contrivance it is obvious, that as the rods BC , BD , turn upon the centres A , B , in contrary directions, the piston rod will be made to move in the right

Fig. 2

Fig. 3.

Fig. 1.

line PM without deviation; NM being the length of the stroke. The relative lengths of the bars AC , CL , may be varied at pleasure; but those we have mentioned will be found as well as any in practice.

5. A piston rod may also be kept from deviating to either side, while it gives motion to a crank, and *vice versa*, thus: place a cross bar at a distance from the end of the cylinder, rather greater than the stroke of the piston, and make the piston rod play in a hole made in the cross bar; let an axle be fixed to a proper point of the piston rod between the end of the cylinder and the cross bar, and from this axle let two equal connecting rods pass to the crank, one on each side the cross bar: by this simple contrivance, the alternating and circular motions may be communicated to the different parts of the machine with great facility.

6. A rectilinear vertical motion may, again, be produced thus:—Two of the adjacent angles of a parallelogram are made to describe concentric circles, so that the side between them passes through their centre, and one of the remaining angles another circle having its convexity opposed to that of the two former, then the fourth angle of the parallelogram will describe a line that differs insensibly from a straight line. This construction is the invention of Watt, and now very common.—*Gregory's Mechanics*.

PARALLEL, in Geometry, is applied to lines, figures, and bodies, which are every where equidistant from each other, or which, if ever so far produced, would never meet.

PARALLEL *Right Lines*, are those which, though infinitely produced, would never meet; which is Euclid's definition. To draw a line CD parallel to a given line AB through a given point P . From P draw any line meeting AB in some point Q ; then make the angle $QPD =$ the angle AQP , so shall DP be the parallel line required. This in practice is better done by a parallel ruler.

PARALLEL *Ruler*, an instrument consisting of two wooden, brass or steel rulers, AB and CD , equally broad throughout,

and so joined together by the cross blades EF and GH , as to open to different intervals, and accede and recede, yet still retain their parallelism. The use of this instrument is obvious; for one of the rulers being applied to a given line, another drawn along the extreme edge of the other, will be parallel to it; and thus, having given only one line, and erected a perpendicular upon it, we may draw any number of parallel lines or perpendiculars to them, by only observing to set off the exact distance of every line with the point of the compasses. But the best parallel rulers are those whose bars cross each other, and turn on a joint at their intersection; one of each bar moving on a centre, and the other ends sliding in grooves as the rulers recede.

PARALLELS of *Latitude*, in Astronomy, are lesser circles of the sphere parallel to the ecliptic, imagined to pass through every degree and minute of the colures.

PARALLELS of *Altitude*. Almucantars, are circles parallel to the horizon, imagined to pass through every degree and minute of the meridian between the horizon and zenith, having their poles in the zenith. They are represented on the globe by the division on the quadrant of altitude, in its motion about the body of the globe, when screwed to the zenith.

PARALLELS of *Declination*, in Astronomy, are the same with parallels of latitude in Geography.

PARALLEL *Sphere*, that situation of the sphere wherein the equator coincides with the horizon, and the poles with the zenith and nadir. In this sphere all the parallels of the equator become parallels of the horizon, consequently no stars ever rise or set, but all turn round in circles parallel to the horizon; and the sun, when in the equinoctial, wheels round the horizon the whole day. After his rising at the elevated pole, he never sets for six months; and after his entering again on the other side of the line, never rises for six months longer.

PARALLEL Sailing, in Navigation, is the sailing under a parallel of latitude. See NAVIGATION.

PARALLELISM of the Earth's Axis, is used to denote that invariable position of the terrestrial axis, by which it always points to the same point in the heavens, abstracting from the trifling effect of nutation, &c. See NUTATION.

PARALLELOGRAM, in Geometry, is a quadrilateral right-lined figure, whose opposite sides are parallel.

PARALLELOGRAM receives particular denominations, according to the equality or inequality of its sides and angles. Thus, a *rectangle*, *rhombus*, *rhomboid*, and *square*, are each a particular species of parallelograms, for the properties of which see the several articles. Other properties, common to every parallelogram, may be enumerated as follows:—1. A parallelogram has its opposite sides and angles equal to each other, and the diagonal divides it into two equal triangles. 2. The two adjacent angles of any parallelogram are, together, equal to two right angles. 3. Parallelograms having equal bases and altitudes, are equal; on equal bases they are to each other as their altitudes; and with equal altitudes they are to each other as their bases; and generally parallelograms are to each other in the compound ratio of their bases and altitudes. 4. The sum of the squares of the diagonals of any parallelogram, is equal to the sum of the squares of the four sides. 5. The complements about the diagonals of any parallelogram are equal to each other.

PARALLELOGRAM of Forces, is a term used to denote the composition of forces, or the finding a single force that shall be equivalent to two or more given forces when acting in given directions.

PARALLELOPIPED, in Geometry, a regular solid, comprehended under six sides, or parallelograms, the opposite ones of which are similar, parallel, and equal to each other.

PARALLOGISM, in Logic, a false reasoning, or a fault committed in demonstration, when a consequence is drawn from principles that are false; or, though true, are not proved; or when a proposition is passed over that should have been proved by the way.

PARAMETER, a certain and constant right line in each of the three conic sections, and otherwise called the *Latus Rectum*.

PARAMOUNT, the supreme or highest lord of the fee.

PARAPET, in Fortification, an elevation of earth designed for covering the soldiers from the enemy's cannon or small shot.

PARAPHERNALIA, are the women's apparel, jewels, and other things, which in the life-time of her husband she wore as the ornaments of her person, to be allowed by the discretion of the court, according to the quality of her and her husband. The husband cannot devise such ornaments and jewels of his wife, though during his life he has power to dispose of them. But if she continues in the use of them till his death, she shall afterwards retain them against his executors and administrators, legatees, and all other persons, except creditors where there is a deficiency of assets. 2 Black. 436.

PARAPHRASE, an explanation of some text, in clearer and more ample terms, whereby is supplied what the author might have said or thought on the subject; such are esteemed Erasmus's Paraphrase on the New Testament, the Chaldee Paraphrase on the Pentateuch, &c.

PARASANG, an ancient Persian measure, different at different times, and in different places; being sometimes 30, sometimes 40, and sometimes 50 stadia or furlongs.

PARASELINE, a mock moon, seen usually in a ring surrounding the moon.

PARASITES, or **PARASITICAL Plants**, in Botany, such plants as are produced out of the trunk or branches of other plants, from whence they receive their nourishment, and will not grow upon the ground; as the mistletoe, &c.

PARBUCKLE, is a contrivance to haul up or lower down a cask, &c. where there is no crane or tackle; it is formed by passing the middle of a rope round a post or ring, or under a boat's thwart; the two parts of the rope are then passed under the two quarters of the cask, bringing the two ends back again over it, which being both hauled or slackened together, either raise or lower the barrel, &c. as may be required.

PARCELLING, long narrow slips of canvass, and frequently bound about a rope in the manner of bandages, previous to its being served. It is laid in spiral twines as smoothly upon the surface as possible, that the rope may not become uneven and full of ridges. Parcelling is also used to raise a mouse on the stays, &c. and is firmly fastened by marline from one end to the other. *Parcelling a Seam*, is the laying a slip of canvass upon it, and daubing it over with melted pitch.

PARCEL MAKERS, two officers in the exchequer, who make parcels of the escheators' accounts, in which they charge them with every thing they have levied for the king's use, within the time of their office, and deliver the same to one of the auditors of the court to make their accounts therewith.

PARCHMENT, is the skin of sheep or goats, prepared for writing, and covering books. The skin is stripped of its wool, and passed through the lime pit. The skinner then stretches it on a frame, perforated longitudinally with holes furnished with wooden pins that may be turned at pleasure, like those of a violin, to stretch the skin like a drum head. The skin being thus sufficiently stretched on the frame, the flesh is pared off with a sharp instrument; it is then moistened with a rag, and white chalk reduced to a fine dust, strewed over it; then with a large pumice stone, the workman rubs over the skin, and thus scours off the remains of the flesh. They then go over it again with an iron instrument; moisten it as before, and rub underneath with pumice stone without any chalk; this smooths and softens the flesh side very considerably. They drain it again, by passing over it the iron instrument as before. The flesh side thus drained, they pass the iron on the hair side; then stretch it tight on the frame by means of the pins, and go over the flesh side again with the iron; this finishes its draining: the more the skin is drained, the whiter it becomes. They now throw on more chalk, sweeping it over with a piece of lamb skin that has the wool on; this smooths it further, and gives it a white knap. When dried, it is taken off the frame, by cutting all round. The skin, thus far prepared by the skinner, is taken by the parchment-maker; who first scrapes or pares it dry on the summer, which is a calfskin stretched in a frame, with an iron instrument like that above named, only finer and sharper; with this, worked with the arm from the top to the bottom of the skin, he takes away one-half of its thickness, and the skin thus equally pared on both sides, is rubbed with the pumice stone to smooth it. This last preparation is performed on a bench covered with a sack stuffed with flocks, and it leaves the parchment fit for writing upon.

VELLUM, made from the skins of sucking calves, possesses a finer grain than parchment, but it is prepared in the same manner, without however being passed through alum water.

PARDIES, **IGNATIUS GASTON**, an ingenious French mathematician, was born in the province of Gascony, in 1636, and died in 1673, when only 37 years of age.

PARDON, in a religious sense, is an exercise of the divine placability towards repentant offenders. It is nearly the same as grace and favour, and is conferred on those who comply with the terms or conditions of the gospel, which are faith, repentance, and future obedience. It is a result of the sovereignty of Almighty God; and is therefore given without any consideration of reward, satisfaction, or advantage to the offender.

PARDON, in a legal sense, is the remitting or forgiving a felony, or other offence committed against the king. Blackstone mentions the power of pardoning offences to be one of the greatest advantages of monarchy in general, above every other form of government; and which cannot subsist in democracies. Its utility and necessity are defended by him on all those principles which do honour to him and human nature. See 4 Black. 496. Pardons are either general or special: general, as by act of parliament, of which, if they are without exceptions, the court must take notice *ex officio*; but if there are exceptions therein, the party must aver that he is none of the persons excepted. 3 Inst. 233. Special pardons are either of course, as to persons convicted of manslaughter, or *de facto*, and by several statutes to those who shall discover their accomplices in several felonies; or of grace, which are by the king's charter, of which the court cannot take notice *ex officio*, but they must be pleaded. 3 Inst. 283.

A pardon may be conditional, that is, the king may extend his mercy upon what terms he pleases; and may annex to his bounty a condition either precedent or subsequent, on the performance whereof the validity of the pardon will depend, and this by the common law. 2 Hawk. 37.

PARENT, ANTHONY, a reputable French mathematician, was born in Paris in 1666, and died in 1716, having at his death numerous manuscripts on various mathematical and philosophical subjects.

PARENTS AND CHILDREN. If parents run away and leave their children at the charge of the parish, the churchwardens and overseers by order of the justices may seize the rents, goods, and chattels, of such parents, and dispose thereof towards their children's maintenance. A parent may lawfully correct his child, being under age, in a reasonable manner; but the legal power of the father over the persons of his children ceases at the age of 21. 1 Black. 452. See **INFANT**.

PARENTHESIS, in Grammar, certain intercalary words inserted in a discourse, which interrupt the sense or thread, but seem necessary for the better understanding, of the subject.

PARHELION, a mock sun, or meteor of a bright colour, appearing on one side of the sun. Parhelia are more rarely seen than halos, but their appearance is singularly curious. Their apparent size is generally the same as the true sun; but they are not always round, nor always so bright as the sun; and when several appear, some are brighter than others. They are tinged externally with colours like the rainbow; and many of them have a long fiery tail, opposite to the sun, becoming paler towards the extremity. These tails mostly appear in a white horizontal circle, commonly passing through all the parhelia, and would go through the centre of the sun if it were entire. We have on record an account of parhelia seen at Rome, in March, 1620: at this time four were observed, one of which was very much tinged with various colours like the rainbow; and the others were faintly so. Some were also observed by Cassini, in 1683. In England and Scotland two have frequently been seen at a time. In North America they are often seen, and continue four hours, nay, sometimes for several days, being visible from sun-rise, to sun-set; when these disappear, rain or snow is there generally expected. Mr. Huygens, on applying his attention to these appearances, was soon sensible that they could not arise from such globules as formed the halos; yet since parhelia are always attended with halos, he was satisfied that their causes must be much alike. Considering, then, what other figures hail-stones might possibly have, besides a spherical one, he could find no other so simple as that of a cylinder; and, indeed, he had often observed, that snow consisted of several slender oblong particles, mixed with those of other shapes; and seeing that small globules were sufficient for the production of halos, he imagined that a great number of small cylinders, floating in the air, might produce similar appearances. He also remembered that Descartes had taken notice of several small columns, which he had seen lying on the ground, the extremities of which were bounded with flat star-like figures, consisting of six rays. The large white horizontal circle, observed in some of these phenomena, M. Huygens supposed to be produced by the reflection of the sun's rays from the outsides of the upright cylinders; since, when the sun shines upon a number of such cylinders suspended in the air, a white circle must necessarily appear to pass through the sun parallel to the horizon. This he shews very distinctly by a large figure of a cylinder, and by pointing out the progress of the sun's rays reflected from it. For every point of the sun's vertical diameter, as well as his centre, will illuminate a circle of cylinders, of the same apparent height as the illuminating point:—It is observable that no thick clouds are seen in the air when these circles appear; but only such as are very thin, and scarcely visible. For in most of these observations the sky is said to have been very clear and serene; which agrees quite well with this hypothesis; since these minute cylinders must constitute a very thin cloud uniformly extended, through which the sun, and even the colour of the sky, may be seen. See **HALOS**.

PARIS, Herb Paris, or *Truelove*, a genus of plants belonging to the octandria class, and in the natural method ranking under the eleventh order samentæ.

PARIS, Plaster of, is burnt alabaster, which absorbs water so rapidly that in a few minutes it dries and becomes hard, so that it is greatly employed in making casts for figures, and in ornamental work among plasterers.

PARISH. In England there are 9913 parishes, of which 3845 are churches impropriate, and the rest are annexed to colleges or church dignities. In many of these parishes, on account of their large extent, and the number of parishioners, there are several chapels of ease. Parish signifies the precinct of a parish church, and the particular charge of a secular priest. Formerly a parish was synonymous with diocese, and the tithes were paid to any priest whom the party chose; but it was found convenient to allot a certain district for each priest, that he alone might receive the tithe. It is very doubtful when they originated. Some place the division of parishes in A.D. 650, others in 1179. A parish may contain one or more villa, but it is presumed to contain only one, and anciently was co-extensive with the manor. Money given by will to a parish is given to the poor. Sometimes by act of parliament a large parish is subdivided into two or more.

The extent of parishes is very different in different parts of England. In the northern counties some parishes contain from twelve to twenty cures of souls, each of the extent of a parish in the southern counties. This is supposed to have arisen from the scanty population at the time of the first division.

PARISH CLERK. In every parish, the parson, vicar, &c. has a parish-clerk under him, who is the lowest officer of the church. These were formerly clerks in orders, and their business at first was to officiate at the altar, for which they had a competent maintenance by offerings, but now they are almost always laymen, and have certain fees with the parson on christenings, marriages, burials, &c. besides wages for their maintenance. He must be twenty years of age, and of honest conversation, and is generally appointed by the minister, unless there is a custom for the churchwardens and parishioners to elect. It is an office for life, and a freehold. He may make a deputy without license of the bishop.

PARISHIONER, an inhabitant of or belonging to any parish, lawfully settled there. Parishioners are a body politic to many purposes: as, to vote at a vestry if they pay scot and lot, and they have a sole right to raise taxes for their own relief, without the interposition of any superior court; may make by-laws to mend the highways, and to make banks to keep out the sea, and for repairing the church, and making a bridge; and for making and maintaining fire engines. They may also purchase workhouses for the poor, or any such thing for the public good.

PARISH-OFFICERS, officers chosen annually to regulate and manage the concerns of the parish.

PARK, a piece of ground enclosed and stored with wild beasts of chase, which a man may have by prescription or the king's grant. By 16 Geo. III. c. 30, if any person shall pull down or destroy the pale or wall of a park, he shall forfeit 30*l*.

PARLIAMENTS, or GENERAL COUNCILS, in some shape, are of as high antiquity as the Saxon government in this island, and coeval with the kingdom itself. Blackstone, in his valuable Commentaries, says, "It is generally agreed, that in the main, the constitution of parliament, as it now stands, was marked out so long ago as the 17th of king John, A. D. 1215, in the Great Charter granted by that prince; wherein he promises to summon all archbishops, bishops, abbots, lords, and greater barons, personally, and all other tenants in chief, under the crown, by the sheriff and bailiffs, to meet at a certain place, within 40 days' notice, to assess aids and scutages when necessary. And this constitution hath subsisted, in fact, at least from the year 1266, 49 Henry III. there being still extant writs of that date to summon knights, citizens, and burgesses, to parliament." The parliament is assembled by the king's writs, and its sitting must not be intermitted above three years. Its constituent parts are, the king sitting there in his royal political capacity, and the three estates of the realm; the lords spiritual, the lords temporal (who sit together with the king in one house,) and the commons, who sit by themselves in another. The king and these three estates, together, form the great corporation or body politic of the kingdom, of which the king is said to be *caput principium et finis*. For upon their coming

together, the king meets them, either in person, or by representation; without which there can be no beginning of a parliament; and he also has alone the power of dissolving them. It is highly necessary for preserving the balance of the constitution, that the executive power should be a branch, though not the whole, of the legislature. The crown cannot begin of itself any alterations in the present established law; but it may approve or disapprove of the alterations suggested and consented to by the two houses. The legislative therefore cannot abridge the executive power of any rights which it now has by law, without its own consent: since the law must perpetually stand as it now does, unless all the powers will agree to alter it. And herein indeed consists the true excellence of the English government, that all the parts of it form a mutual check upon each other. In the legislature, the people are a check upon the nobility, and the nobility a check upon the people; by the mutual privilege of rejecting what the other has resolved: while the king is a check upon both, which preserves the executive power from encroachments.

The lords spiritual consist of two archbishops and twenty-four bishops. The lords temporal consist of all the peers of the realm, the bishops not being in strictness held to be such, but merely lords of parliament. Some of the peers sit by descent; some by creation: others, since the union with Scotland, by election, which is the case of the sixteen peers, who represent the body of the Scots nobility. The peers for Ireland, at present, are 28, but the number is indefinite, and may be increased at will by the power of the crown.

A body of nobility is more peculiarly necessary in our mixed and compounded constitution, in order to support the rights of both the crown and the people; by forming a barrier to withstand the encroachments of both. It creates and preserves that gradual scale of dignity, which proceeds from the peasant to the prince; rising like a pyramid from a broad foundation, and diminishing to a point as it rises. The nobility therefore are the pillars, which are reared from among the people, more immediately to support the throne; and if that fails, they must also be buried under its ruins. Accordingly, when in the 17th century the commons had determined to extirpate monarchy, they also voted the house of lords to be useless and dangerous.

The commons consist of all such men of any property in the kingdom, as have not seats in the house of lords; every one of which has a voice in parliament, either personally, or by his representatives. This, however, must be understood with some limitation. Those who are possessed of land estates, though to the value of only 40s. per annum, have a right to vote for members of parliament; as have most of the members of corporations, boroughs, &c. But there are very large trading towns, and populous places, which send no members to parliament; and of those towns which do send members, great numbers of the inhabitants have no votes. Many thousand persons, of great personal property, have, therefore, no representatives. Indeed, the inequality and defectiveness of the representation has been justly considered as one of the greatest imperfections in the English constitution. The extension of parliaments to seven years, has also been viewed in the same light.

The house of commons, in the reign of Henry VI. consisted of 300 members. In Sir E. Coke's time they amounted to 493. In 1707, they were augmented to 513, for England and Wales; but the union with Scotland taking place in the above year, forty-five representatives were added for that country. In 1801, when the union with Ireland was effected, an additional 100 was introduced, so that the whole house of commons now consists of 638 members; viz. 80 knights for 40 counties in England; 50 citizens for 25 cities, (Ely sending none, and London four,); 334 burgesses for 167 boroughs, and five burgesses for five boroughs, viz. Abingdon, Banbury, Bewdley, Higham Ferrers, and Monmouth; four burgesses for the two universities of Oxford and Cambridge; 16 barons for the eight cinque ports, viz. Hastings, Dover, Sandwich, Romney, Hythe, and their three branches, Rye, Winchelsea, and Seaford; 12 knights for 12 counties in Wales; 12 burgesses for 12 boroughs in that country; 30 knights for the shires of Scotland, and 15 burgesses for its boroughs; 64 knights and 36 burgesses for Ireland. Every member, though chosen by one particular district, when elected and returned, serves for the whole realm. For the end of his coming thither is

not particular, but general; not merely to serve his constituents, but also the commonwealth, and to advise his majesty, as appears from the writ of summons.—To prevent bribery, the following oath is provided to be administered to every voter prior to his being polled:—"I, _____, do swear (or being one of the people called Quakers, do solemnly affirm,) I have not received or had, by myself, or any person whatsoever in trust for me, or for my use and benefit, directly or indirectly, any sum or sums of money, office, place or employment, gift or reward, or any promise or security for any money, office, or employment, or gift, in order to give my vote at this election: and that I have not before been polled at this election. So help me God."

These are the constituent parts of a parliament; the king, the lords spiritual and temporal, and the commons. Parts, of which each is so necessary, that the consent of all three is required to make any new law that should bind the subject. Whatever is enacted for law for one, or by two only, of the three, is no statute; and to it no regard is due, unless in matters relating to their own privileges. The power and jurisdiction of parliament, says Edward Coke, is so transcendent and absolute, that it cannot be confined, either for causes or persons, within any bounds. It hath sovereign and uncontrollable authority in making, confirming, enlarging, restraining, abrogating, repealing, reviving, and expounding of laws, concerning matters of all possible denominations, ecclesiastical, or temporal, civil, military, maritime, or criminal: this being the place where that absolute despotic power, which must in all governments reside somewhere, is entrusted by the constitution of these kingdoms. All mischiefs and grievances, operations and remedies, that transcend the ordinary course of the laws, are within the reach of this extraordinary tribunal. It can regulate or new model the succession to the crown; as was done in the reign of Henry VIII. and William III. It can alter the established religion of the land; as was done in a variety of instances, in the reign of king Henry VIII. and his three children, Edward VI., Mary, and Elizabeth. It can change and create afresh even the constitution of the kingdom, and of parliaments themselves; as was done by the act of union, and the several statutes for triennial and septennial elections. It can, in short, do every thing that is not naturally impossible; and therefore some have not scrupled to call its power by a figure rather too bold, the *omnipotence of parliament*. But then their power, however great, was given them in trust, and therefore ought to be employed according to the rules of justice, and for the promotion of the general welfare of the people. And it is a matter most essential to the liberties of the kingdom, that such members be delegated to this important trust, as are most eminent for their probity, their fortitude, and their knowledge; for it was a known apophthegm of the great lord treasurer Burleigh, "that England could never be ruined but by a parliament;" and, as Sir Mathew Hale observes, this being the highest and greatest court, over which none other can have jurisdiction in the kingdom, if by any means a misgovernment should any way fall upon it, the subjects of this kingdom are left without all manner of legal remedy. In order to prevent the mischiefs that might arise, by placing this extensive authority in hands that are either incapable, or else improper, to manage it, it is provided, that no one shall sit or vote in either house of parliament, unless he be twenty-one years of age. To prevent innovations in religion and government, it is enacted, that no member shall vote or sit in either house, till he hath, in the presence of the house, taken the oaths of allegiance, supremacy, and abjuration; and subscribed and repeated the declaration against transubstantiation, the invocation of saints, and the sacrifice of the mass. It is also enacted, that no alien, born out of the dominions of the crown of Great Britain, even though he be naturalized, shall be capable of being a member of either house of parliament.

Some of the most important privileges of the members of either house are, privilege of speech, of person, of their domestics, and of their lands and goods. As to the first, privilege of speech, it is declared by the statute of 1 William and Mary, st. 2. c. 2. as one of the liberties of the people, "that the freedom of speech, and debates, and proceedings in parliament, ought not to be impeached or questioned in any court or place

out of parliament." And this freedom of speech is particularly demanded of the king in person, by the speaker of the house of commons, at the opening of every new parliament. So are the other privileges, of person, servants, lands, and goods. This includes not only privilege from illegal violence, but also from legal arrests, and seizures by process from the courts of law. To assault by violence a member of either house, or his menial servants, is a high contempt of parliament, and there punished with the utmost severity. Neither can any member of either house be arrested and taken into custody, nor served with any process of the courts of law; nor can his menial servants be arrested; nor can any entry be made on his lands; nor can his goods be distrained or seized, without a breach of the privilege of parliament. This exemption, however, from arrests for lawful debts, was always considered by the public as a grievance. The lords and commons therefore generously relinquished their privilege by act of parliament in 1770; and members of both houses may now be sued like other debtors.

The house of lords have a right to be attended, and consequently are, by the judges of the courts of king's bench and common pleas, and such of the barons of the exchequer as are of the degree of the knif, or have been made sergeants at law; as likewise by the masters of the court of chancery; for their advice in point of law, and for the greater dignity of their proceedings. The speaker of the house of lords is generally the lord chancellor, or lord keeper of the great seal, which dignities are commonly vested in the same person. Each peer has a right, by leave of the house as being his own representative, when a vote passes contrary to his sentiments, to enter his dissent on the journals of the house, with the reasons for such dissent; which is usually styled his protest. Upon particular occasions, however, these protests have been so bold as to give offence to the majority of the house, and have therefore been expunged from their journals: but this has always been thought a violent measure, and not very consistent with the general right of protesting.

The house of commons may be properly styled the grand inquest of Great Britain, empowered to inquire into all national grievances, in order to see them redressed. The peculiar laws and customs of the house of commons relate principally to the raising of taxes, and the elections of its members.

With regard to taxes: it is the ancient indisputable privilege and right of the house of commons, that all grants of subsidies, or parliamentary aids, do begin in their house, and are first bestowed by them: although their grants are not effectual to all intents and purposes, until they have the assent of the other two branches of the legislature. The general reason given for this exclusive privilege of the house of commons is, that the supplies are raised upon the body of the people, and therefore it is proper that they alone should have the right of taxing themselves. And so reasonably jealous are the commons of this privilege, that herein they will not suffer the other house to exert any power but that of rejecting; they will not permit the least alteration or amendment to be made by the lords to the mode of taxing the people by a money bill. Under this appellation are included all bills by which money is directed to be raised upon the subject, for any purpose, or in any shape whatsoever; either for the exigencies of government, and collected from the kingdom in general, as the land-tax; or for private benefit, and collected in any particular district, as by turnpikes, parish-rates, and the like.

The method of making laws is much the same in both houses. In each house the act of the majority binds the whole: and this majority is declared by votes openly and publicly given; not as at Venice, and many other senatorial assemblies, privately or by ballot. This latter method may be serviceable, to prevent intrigues and unconstitutional combinations, but is impracticable where a member's conduct must be open to the inspection of his constituents.

To bring a bill into the house of commons, if the relief sought by it is of a private nature, it is first necessary to prefer a petition; which must be presented by a member, and usually sets forth the grievance desired to be remedied. This petition (when founded on facts that may be in their nature disputed) is referred to a committee of members, who examine the matter alleged, and accordingly report it to the house; and then

(or, otherwise, upon the mere petition) leave is given to bring in the bill. In public matters, the bill is brought in upon motion made to the house, without any petition. (In the house of lords, if the bill begins there, it is, when of a private nature, referred to two of the judges, to examine and report the state of the facts alleged, to see that all necessary parties consent, and to settle all points of technical propriety.) This is read a first time, and, at a convenient distance, a second time; and after each reading, the speaker opens to the house the substance of the bill, and puts the question, whether it shall proceed any farther. The introduction of the bill may be originally opposed, as the bill itself may at either of the readings; and if the opposition succeeds, the bill must be dropt for that session; as it must also, if opposed with success in any of the subsequent stages. After the second reading, it is committed, that is, referred to a committee; which is either selected by the house in matters of small importance, or else, if the bill is a matter of great or national consequence, the house resolves itself into a committee of the whole house. A committee of the whole house is composed of every member; and, to form it, the speaker quits the chair (another member being appointed chairman), and may sit and debate as a private member. In these committees, the bill is debated clause by clause, amendments made, the blanks filled up, and sometimes the bill entirely new-modelled. After it has gone through the committee, the chairman reports it to the house, with such amendments as the committee have made; and then the house re-consider the whole bill again, and the question is repeatedly put upon every clause and amendment. When the house have agreed or disagreed to the amendments of the committee, and sometimes added new amendments of their own, the bill is then ordered to be engrossed, or written in a strong gross hand, on one or more long rolls of parchment sewed together. When this is finished, it is read a third time, and amendments are sometimes then made to it; and, if a new clause be added, it is done by tacking a separate piece of parchment on the bill, which is called a rider. The speaker then again opens the contents; and, holding it up in his hands, puts the question whether the bill shall pass. If this be agreed to, the title to it is then settled. After this, one of the members is directed to carry it to the lords, and desire their concurrence; who, attended by several more, carries it to the bar of the house of peers, and there delivers it to their speaker, who comes down from his woolsack to receive it. It there passes through the forms, as in the other house, (except engrossing, which is already done), and if rejected, no more notice is taken, but it passes *sub silentio*, to prevent unbecoming altercations. But if it be agreed to, the lords send a message by two masters in chancery (or, sometimes, in matters of high importance, by two of the judges) that they have agreed to the same; and the bill remains with the lords, if they have made no amendment to it. But if any amendments are made, such amendments are sent down with the bill to receive the concurrence of the commons. If the commons disagree to the amendments, a conference usually follows between members deputed from each house; who, for the most part, settle and adjust the difference: but if both houses remain inflexible, the bill is dropped. If the commons agree to the amendments, the bill is sent back to the lords by one of the members, with a message to acquaint them therewith. The same forms are observed *mutatis mutandis*, when the bill begins in the house of lords. But when an act of grace or pardon is passed, it is first signed by his majesty, and then read once only in each of the houses, without any new engrossing or amendment. And when both houses have done with any bill, it always is deposited in the house of peers, to wait the royal assent; except in the case of a money-bill, which after receiving the concurrence of the lords, is sent back to the house of commons. It may be necessary here to acquaint the reader, that both in the houses, and in their committees, the slightest expression, or most minute alteration, does not pass till the speaker, or the chairman, puts the question; which, in the house of commons, is answered by *aye* or *no*; and, in the house of peers, by *content*, or *not content*.

The giving the royal assent to bills is a matter of great form. When the king is to pass bills in person, he appears on his throne in the house of peers, in his royal robes, with the crown

on his head, and attended by his great officers of state and heralds. A seat on the right hand of the throne, where the princes of Scotland, when peers of England, formerly sat, is reserved for the prince of Wales. The other princes of the blood sit on the left hand of the king; and the chancellor on a close bench removed a little backwards. The viscounts and temporal barons, or lords, face the throne, on benches, or wool-packs, covered with red cloth or baize. The bench of bishops runs along the house to the bar on the right hand of the throne; as the dukes and earls do on the left. The chancellor and judges, on ordinary days, sit upon wool-packs, between the barons and the throne. The common opinion is, that the house sitting on wool, is symbolical of wool being formerly the staple commodity of the kingdom. Many of the peers, on solemn occasions, appear in their parliamentary robes. None of the commons have any robes, excepting the speaker, who wears a long black silk gown; and when he appears before the king it is trimmed with gold. The royal assent may be given two ways; 1. In person. When the king sends for the house of commons to the house of peers, the speaker carries up the money bill or bills in his hand; and, in delivering them, he addresses his majesty in a solemn speech, in which he seldom fails to extol the generosity and loyalty of the commons, and to tell his majesty how necessary it is to be frugal of the public money. It is upon this occasion, that the commons of Great Britain appear in their highest lustre. The titles of all bills that have passed both houses are read; and the king's answer is declared by the clerk of the parliament in Norman-French. If the king consents to a public bill, the clerk usually declares, *le roy le veut*, "the king wills it so to be;" if to a private bill, *soit fait comme il est désiré*, "be it as it is desired." If the king refuses his assent, it is in the gentle language of *le roy s'aviseira*, "the king will advise upon it." When a money-bill is passed, it is carried up and presented to the king by the speaker of the house of commons, and the royal assent is thus expressed, *le roy remercie ses loyal subjects, accepte leur benevolence, et auffi le veut*, "the king thanks his loyal subjects, accepts their benevolence, and wills it so to be." In case of an act of grace, which originally proceeds from the crown, and has the royal assent in the first stage of it, the clerk of the parliament thus pronounces the gratitude of the subject; *le prelat, seigneur, et commons, en ce present parliament assemblez, au nom de tout vous autres subjects, remercient tres humblement votre majesté: et prient a Dieu vous donner en santé bonne vie et longue*; "the prelates, lords, and commons, in this present parliament assembled, in the name of all your other subjects, most humbly thank your majesty, and pray to God to grant you in health and wealth long to live." 2. By the statute 33 Hen. VIII. c. 21. the king may give his assent by letters patent under his great seal signed with his hand, and notified, in his absence to both houses assembled together in the high house, by commissioners consisting of certain peers, named in the letters. And, when the bill has received the royal assent in either of these ways, it is then, and not before, a statute or act of parliament.

This statute or act is placed among the records of the kingdom; there needing no formal promulgation to give it the force of a law, as was necessary by the civil law with regard to the emperor's edicts; because every man in England is, in judgment of law, party to the making of an act of parliament, being present thereat by his representatives. However, copies thereof are usually printed at the king's press, for the information of the whole land. An act of parliament thus made, is the exercise of the highest authority that this kingdom acknowledges upon earth. It hath power to bind every subject in the land, and the dominions thereunto belonging; nay, even the king himself, if particularly named therein. And it cannot be altered, amended, dispensed with, suspended, or repealed, but in the same forms, and by the same authority of parliament; for it is a maxim in law, that it requires the same strength to dissolve as to create an obligation.

Such is the parliament of Great Britain: the source and guardian of our liberties and properties, the strong cement which binds the foundation and superstructure of our government, and the wisely concerted balance, maintaining an equal poise, that no one part of the three estates overpower or distress either of the other.

PARLIAMENT HEEL, the causing a ship to incline a little on one side, so as to clean the upper part of her bottom on the other, and cover it with fresh composition, which latter operation is called boot-topping.

PARODY, a poetical pleasantry, consisting in applying the verses written on one subject, by way of ridicule, to another; or in turning a serious work into a burlesque, by affecting to observe, as nearly as possible, the same rhymes, words, and cadences.

PAROLE, a term signifying any thing done verbally, or by word of mouth, in contradistinction to what is written; thus, an agreement may be by parole. Evidence also may be divided into parole evidence and written evidence. A parole release is good to discharge a debt by simple contract, 2 Show, 417. The holder of a bill of exchange may authorize another to indorse his name upon it.

PARREL, a machine used to fasten the sail-yards of a ship to the mast, in such manner as that they may be easily hoisted and lowered thereon; there are four different kinds of parrels, viz. *Parrel Rope*, is formed of a single rope well served, and furnished with an eye at each end; this being passed round the yard is seized fast on, the two ends are passed round the after part of the mast, and one of them being brought under and the other over the yard, the two eyes are lashed together with a piece of spun yarn; this is seldom used but for the top gallant or smaller yards. *Parrel with Ribs and Trucks*, is formed by passing the two parts of the parrel rope through the two holes in the ribs, observing that between every two ribs is strung a truck on each part of the rope. See the articles *RIB* and *TRUCK*. The ends of the parrel rope are made fast with seizings, these are chiefly used on the top-sail yards. *Parrel with Trucks*, is composed of a single rope passing through a number of trucks sufficient to embrace the mast; these are principally used for the cheeks of a gaff. *TRUSS PARREL*, is formed by fixing a rope upon the middle of the yard, which, passing at the back of the mast, is reeved through an iron thimble, spliced into another rope, (also fastened upon the yard,) and communicates with a tackle reaching to the deck, whereby it may be occasionally slackened or straitened; ships of war generally have two of these, one leading from each side, and they are peculiar to the lower yards.

PARSLEY. The uses of parsley, in cookery, both for sauce and garnish, are numerous and well known. It is, however, poisonous to several kinds of birds; and, although so commonly used at table, facts have been adduced, from which it would appear, that in some constitutions it occasions epilepsy, or at least aggravates the fits in those who are subject to that disease. Inflammation in the eyes has also been attributed to the use of it. Parsley is eaten with great avidity by sheep, and has been recommended for use, in several diseases of those animals, as well as in some diseases of horses. Both the roots and seed are employed in medicine. The former have a sweetish taste, accompanied with a slight warmth, and a flavour somewhat resembling that of the carrot; the latter are warm and aromatic. Parsley is an annual plant, a native of Sardinia, and propagated by seed, which is usually sown about the month of March.

PARSNIPS, are well-known edible roots, which are propagated by seed sown in February or March, and the roots are in perfection about October. These, besides their use as a vegetable for the table, are of great value for the feeding of cattle, horses, sheep, and hogs. Land in Guernsey, which lets for £7 an acre, is sown with parsnips to feed cattle: and the milk of the cows so fed is not only richer than it would otherwise be, but yields butter of fine saffron colour and excellent taste. If washed clean and sliced among bran, horses eagerly devour parsnips; and thrive well, though there is a notion that they are thereby subject to become blind. They fatten sheep and oxen in a short time; and for pigs they are at least equal if not superior to carrots. As food for mankind, they are considered extremely nutritive, and may with great advantage be kept on board ships for long voyages. It is, however, said that they should not be dug up for use in the spring, because, at that season, the nutritive juices rising upward to produce the seed, they are then unwholesome. Parsnips abound in saccharine juice; and various experiments have in vain been made with

a view to extract sugar from them. In some parts of Ireland they are used instead of malt in brewing: and, when properly fermented, afford an agreeable beverage. The seeds are said in some cases to have proved an efficacious remedy in intermitted fevers.

PARSON, signifies the incumbent of a church. He is in himself a body corporate, in order to protect and defend the rights of the church by a perpetual succession. When a parson is instituted and inducted into a rectory, he is then, and not before, in full and complete possession. 1 Black. 391.

PART, in Music, the name of each of the melodies of any harmonic composition, and which, when performed in union, form its harmony. Four is the fewest number of parts with which the chords necessary to elaborate harmony, can be completely filled.

PARTERRE, in Gardening, a level division of ground, which, for the most part faces the south and best front of a house; and is generally furnished with evergreens, flowers, &c.

PARTICLE, the minute part of a body, or an assemblage of several atoms of which natural bodies are composed. This term is frequently used as synonymous with atom, corpuscule, and molecule, but sometimes it is distinguished from them.

PARTIES, in Law, signify the persons that are named in a deed or fine, viz. those that made the deed, or levied the fine, and also those to whom the same was made or levied.

PARTING, in Chemistry and Metallurgy, is an operation by which gold and silver are separated from each other. In this sense it is the same with refining metals, or obtaining them in a pure state. Gold and silver are called perfect metals, because they are capable of withstanding the action of very strong heat. All other metals are reduced to the state of oxides when subject to fire with access of air. Gold and silver may therefore be purified from baser metals, by keeping them melted till the alloy be destroyed. But this process is tedious and expensive, from the great consumption of fuel. A shorter and more advantageous method of refining gold and silver has been discovered. A certain quantity of lead is put into the crucible with the alloy of gold and silver, the whole is exposed to the action of the fire; and the lead being quickly converted by heat into an oxide, which is easily melted into a semi-vitrified and powerful vitrifying matter, called litharge, we have only to increase the proportion of imperfect metals, the litharge will prevent them from being so well covered and protected by the perfect metals; and by uniting with these imperfect metals, it communicates to them its property of being very easily oxidated. By its vitrifying and fusing property, exercised with force upon the calcined and naturally refractory parts of the other metals, it accelerates the fusion, scorification, and separation of these metals. In this operation the lead is scorified, and scorifies along with it the imperfect metals. It separates from the metallic mass, floats upon the surface of the melted mass, and becomes vitrified. But as the litharge would soon cover the melted metal, and by preventing the access of air, prevent the oxidation of the remaining imperfect metals, such vessels are employed as are capable of imbibing and absorbing in their pores the melted litharge, and thus removing it out of the way. Or, for large quantities, vessels are so constructed, that the fused litharge, besides being soaked in, may also drain off through a channel made in the corner of the vessel.

Vessels made of lixiviated wood or bone ashes, are most proper for this purpose. These vessels are called *cupels*, the process itself *cupellation*. The cupels are flat and shallow. The furnace should be vaulted, that the heat may be reverberated upon the surface of the metal during the operation. A crust, or dark-coloured pellicle, is continually forming upon the surface. When all the imperfect metal is destroyed, and the scorification has ceased, the surface of the perfect metal is seen clean and brilliant, forming a kind of fulguration, called *lightning*. By this mark, the metal is known to be refined.

Purification of Gold by Antimony—When gold contains but a small quantity of alloy, it may be separated from the base metal by melting it in a crucible that will hold twice its quantity, throwing upon it, whilst in fusion, double its weight of crude antimony (sulphuret of antimony). The crucible is then covered, and the whole kept in a state of fusion for some minutes; and when the surface sparkles, it is poured into an

inverted cone which has been previously heated and greased. By striking the cone on the ground, the metal will come out when cold. The mass consists of two substances; the upper part being the sulphur of the crude antimony, united with the impure alloy; and the lower part gold, united to some of the regulus of antimony. This gold may be separated from the regulus of antimony by exposure to less heat than will melt the gold, because antimony is volatile, and dissipates in such a heat. If the gold is not sufficiently purified by this first process, repeat it a second, and even a third time. When a part has been dissipated, more heat is required to keep the gold in fusion; the fire must therefore be increased towards the conclusion of the operation. The purification may be completed by throwing into the crucible a little crude antimony, which effectually calcines the remaining regulus of antimony. If, after these operations, the gold be deprived of its usual ductility, this may be restored by fusing it with nitre and borax. The sulphur of the antimony, though it unites with the basest metals, does not destroy them, but forms with them a scoria, from which they may be separated by treatment as an ore. Diagrams of crucibles are unnecessary; every one knows that a crucible is shaped like a wine glass. When the quantity of silver mixed with the gold is considerable, they may be separated by other processes. Nitric acid, muriatic acid, and sulphur, which cannot dissolve gold, attack silver very easily; these three agents furnish methods of separating silver from gold, and the operation is called *parting*. Parting by nitric acid being the most convenient, is almost the only one employed by goldsmiths and coiners, who call it simply *parting*. That performed by muriatic acid is only made by cementation, and receives the name of concentrated *parting*. Lastly, *parting* by sulphur is effected by fusion; it is called *dry parting*.

Parting Gold from Silver by Nitric Acid—Though *parting* by nitric acid be easy, it cannot succeed exactly, unless we attend to some essential circumstances. The gold and silver must be in a proper proportion; for if the gold be in too great a quantity, it would cover the silver, and guard it from the action of the acid; therefore when assayers know not the proportions of gold to silver in the mass, they rub the mass on a touch-stone of black basalt, so as to leave a mark upon it; they then make similar marks with their proof-needles, (needles composed of gold and silver alloyed in graduated proportions,) and by comparing the colour of the several marks, they discover the probable scale of admixture. If the trial shows that in a given mass the silver is not to the gold as three to one, it will not serve for the operation of *parting* by aqua-fortis, and the quantity of silver necessary to make an alloy of that proportion must be added. This operation is called *quartation*, because the gold is reduced to a fourth of the whole mass. No inconvenience arises from the quantity of silver being too great, except a waste of aqua-fortis. The nitric acid, or aqua-fortis, employed, must be pure, and free from sulphuric and muriatic acids. Its purity must therefore be ascertained; and if this be found not sufficient, the acid must be purified by nitrate of silver. If the purity of the nitric acid were not attended to, a great quantity of silver proportionable to these two foreign acids, would be separated during the solution; and this portion of silver converted by these acids to sulphate of silver, and to muriate of silver, would remain mingled with the gold. When the metallic mass is properly alloyed, it is to be reduced to plates called *cornets*, or to grains, rolled up spirally. These are put into a matras, and upon them there is poured a quantity of aqua-fortis, whose weight is to that of silver as three to two; and as the nitric acid employed for this operation is weak, the solution is at first assisted by the heat of a sand bath, on which the matras is placed. When no further mark of solution appears, the aqua-fortis charged with silver is decanted. Fresh nitric acid, stronger than the former, but in less quantity, is poured into the matras. This is boiled in the remaining mass, and decanted as the former. Aqua-fortis must be boiled a third time on the remaining gold, that all the silver be dissolved. The gold then washed with boiling water, is very pure, if the operation has been performed with due attention. It is called, *gold of parting*.

The silver dissolved in aqua-fortis may be separated by distillation. In this case all the aqua-fortis is recovered pure, and fit

for another parting. Or it may be precipitated by some substance having a greater affinity than this metal with nitric acid. In the ascent, copper is generally employed for this purpose. The solution of silver is put into copper vessels. The aqua-fortis dissolves the copper, and the silver precipitates; the new solution being decanted, is then a solution of copper. The precipitate is well washed, and melted into an ingot, called parted silver. When this silver has been obtained from a mass which had been refined by lead, and when it has been well washed from the solution of copper, it is very pure. Or the silver may be separated from the nitric acid by adding to it muriatic acid, with which it forms muriate of silver. Muriate of silver may be decomposed by mixing it with soda, and exposing it to a sufficient heat in a crucible; by this means the soda unites to the muriatic acid, and sets the silver free.

Verditer.—The refiners frequently employ this solution of copper obtained in the process of parting, for making verditer; which is prepared by adding quick lime to the solution: a precipitate takes place, which is the blue pigment known by the name of verditer.

Parting Gold from Silver by Cementation.—This is also called concentration, when the quantity of gold is so great to that of the silver, as to render it a difficult task by aqua-fortis. The mixed metal to be cemented is reduced to plates as thin as small pieces of money. At the bottom of the crucible, or melting pot, is laid a stratum of cement, composed of four parts of brick dust, one part of green copperas (sulphate of iron) calcined to redness, and one part of common salt, about the thickness of a finger in depth. Upon this stratum a layer of plates of the metal is placed, and then another stratum of cement, and so on till the crucible is filled. It is now placed in a furnace, or oven (after a top has been luted on the crucible), and exposed for twenty-four hours, till it becomes red-hot, but not melted. The fire is now left to go out, and the metal to cool, that it may be separated from the cement, and boiled repeatedly in pure water. This gold is afterwards tried on a touch-stone; and if not sufficiently purified, the process is performed a second time. By the above method, we see how powerfully silver is dissolved by marine acid, when in a state of subtile vapour, that has been disengaged from the common salt of the cement. Nitro may be used instead of common salt, as the nitrous acid readily dissolves silver; but the mixing of common salt and nitre together is highly injudicious, because the joint acids are liable to dissolve some of the gold with the silver. Whatever silver has been separated, will now remain in the cement: but it may be freed from this by lead, in the method described in cupellation.

Parting Gold from Silver in the Dry Way.—This, called also parting by fusion, is performed by means of sulphur, which has the property of uniting easily with silver, while it does not attack gold. This dry parting, is troublesome and expensive, and is not undertaken but when the silver far exceeds the gold, because sulphur will not separate it so easily as aqua-fortis, and will therefore require a farther application to cupellation and solution.

Refining Silver by Nitre.—The principle of this operation is founded on the property of nitre to oxydate very powerfully all base metals; whereas the precious metals are not affected by it. For as the metallic oxides and glasses remain not united with reguline metals, and as these latter, when in fusion, sink to the bottom on account of their great specific gravity, they may be easily parted from the scoria. The silver to be purified by nitre is first granulated, then mixed with a fourth part of its weight of dry nitre, an eighth part of potash, and a little common glass, all in powder. This mixture is put into a crucible, two-thirds full. The crucible is covered with a smaller crucible inverted, in the bottom of which a small hole has been made. Both are luted, and placed in a furnace capable of drawing air to make the fire intense enough to melt the silver. Then into the furnace charcoal is put to such a height, that only the top of the inverted crucible shall be uncovered. The coal is then kindled, and the vessels made moderately red, and a hot coal put upon the small hole in the bottom of the inverted crucible, a shining light be observed round this coal, and a loud noise at the same time heard, the operation proceeds. The fire is now sustained at the same degree till

cease, when it is increased, so that the silver be well melted, and then the crucibles are taken out of the furnace. The large crucible is broken when it is cold, and the silver will be found at the bottom covered with green alkaline scoria. Some silver is apt to be lost in this operation, by the swelling and detaching of the nitre, which often forces it through the hole in the upper crucible, unless great care be used; this method has, however, its advantages, being more expeditious than cupellation.

Separating Silver from Copper by Eliquation.—When in a large way, it is desired to separate a small quantity of silver from much copper with which it is alloyed, the process called eliquation is resorted to. The operation depends on the nearer affinity of silver with lead than with copper: hence it fuses, and combines with lead at a degree of heat in which copper does not fuse.

Whitening Silver by Boiling.—The whitening of silver by boiling is one of the methods of parting copper from silver in the humid way. The silver wrought in any shape is first ignited to redness, then boiled in a ley of muriate of soda and acidulous tartrate of potash, and by so doing the copper is removed from the surface, and the silver receives a whiter appearance.

Precipitating Silver by Copper.—Copper has a much greater affinity with oxygen than silver; hence the silver is precipitated from its solutions as a fine silver dust, by metallic copper. This likewise affords a means of discovering what portion of silver may be contained in an alloy of silver and copper. A quantity of the mixture determined by weight is dissolved in nitric acid; the solution is diluted with filtered water, and a plate of copper hung in it, till no more precipitate. The weight of the precipitate, when edulcorated, is then compared with that of the whole alloyed metal put to trial. This silver dust, well washed, and mixed with gum water, is used in water painting.

Separating Silver from Copper by an Alkaline Sulphuret. The affinity of copper with sulphur is stronger than that of silver; hence liver of sulphur (sulphuret of potash) has been proposed as an expedient to free silver from copper; for if silver containing copper be fused with alkaline sulphuret, the base metal will combine with the latter, and be converted into scoria floating on the silver.

Kerr's Mode of Separating Silver from Copper.—A compound acid that will act exclusively upon silver, is made by dissolving one pound of nitrate of potash (common nitre or saltpetre), in eight or ten pounds of sulphuric acid (oil of vitriol), or by mixing sulphuric and nitric acids. This acid dissolves silver easily, while it will not attack copper, iron, lead, gold, or platinum.

These properties have rendered it capable of a very useful application in the arts. Among the manufactures at Birmingham, that of making vessels of silver, plated on copper, is a very considerable one; and the method of effecting the separation of silver and copper, by means of the above mentioned compound of sulphuric acid and nitre is now commonly practised by the manufacturers at Birmingham, and is much more economical, and much easier executed, than any method previously practised; nothing more is necessary than to put the pieces of plated metal into a glazed earthen pan, pour upon them some of the acid liquor, stir them about, that the surface may be frequently exposed to fresh liquor, and assist the action by a gentle heat, from 100° to 200° of Fahrenheit's thermometer. When the liquor is nearly saturated, the silver is precipitated from it by common salt, forming muriate of silver, or lusa cornea, easily reducible to a metallic state, by melting it in a crucible with a sufficient quantity of potash; and lastly, by refining the melted silver, if necessary, with a little nitre thrown upon it. In this manner the silver will be obtained sufficiently pure, and the copper will remain unchanged. Either the silver may be precipitated in its metallic state, by adding to the solution of silver a few of the pieces of copper, and a sufficient quantity of water to enable the liquor to act upon the copper.

A Method of obtaining Gold in a Pure State.—Perfectly pure gold may be obtained by the addition of commerce in alcohol, by adding a weak solution of nitric acid, after being well washed.

—Dissolve the

in the market

*Lord's Butte Furnace,
constructed by Messrs. Hoyle.*

The new Hydro-Pneumatic Pump.

be formed. To reduce this to the metallic state, mix one-part of it with three of soda, expose the whole to a white heat, and when the mixture is well fused, suffer it to cool; then break the crucible, and separate the pure silver from the muriate of soda which has been formed.

PARTING, the state of being driven from the anchors, by breaking the cables through the violence of the wind, waves, &c.

PARTITION, is a dividing of lands descended by the common law, or custom, among coheirs or parceners, where there are two at the least.

PARTNER. If there are several joint partners, and a person has dealings generally with one of them in matters concerning their joint trade, whereby a debt becomes due to the said person, it shall charge them jointly, and the survivors of them; but if the person only dealt with one of the partners upon a separate account, in that case the debt shall only affect that partner and his executors. If one or more of the joint traders become bankrupt, his or their proportions are only assignable by the commissioners, to be held in common with the rest who are not bankrupts. If one of two partners become a bankrupt, the commissioners cannot meddle with the interest of the other, for it is not affected with the bankruptcy of his companion. Payment to one of the partners, is payment to them all.

PARTNERS, in Naval matters, pieces of planks nailed round the several scuttles or holes in a ship's decks, wherein are contained the masts and capstans; they are used to strengthen the deck where it is weakened by those breaches, but particularly to support it when the mast leans against it. *Partners*, is also a name given to the scuttles themselves.

PARTNERSHIP, a contract among two or more persons to carry on a certain business, at their joint expenses, and share the gain or loss which arises from it. All debts contracted under the firm of a company are binding on the whole of the partners, though the money was borrowed by one of them for his own private use, without the consent of the rest. When a partner in a company becomes insolvent, the company is not bound for his debts beyond the extent of his share. Partnership is dissolved by the death of a partner; yet where there are more than two, it may be renewed by agreement.

PART-OWNERS, are partners interested, and possessed of certain shares in a ship. Owners are tenants in common with each other; but one or more joint-owners refusing to contribute their quota to the outfit of the vessel, cannot prevent her from going to sea against the consent of the majority of the owners, who, giving security in the Admiralty, may freight the ship at their own exclusive risk, by which the smaller dissentient number of owners will be excluded at once from any share, either in the risk or in the profits.

PARUS, or **TIRMOUSE**, in Ornithology, a genus belonging to the order *passeres*, of which there are fourteen species.

PASCAL, **BLAISE**, a very excellent French mathematician and philosopher, was born at Clermont, in Auvergne, in 1623. He discovered very early an extraordinary genius for mathematical and philosophical inquiries, and is said to have formed a system of geometry, at the age of twelve years, without having seen any work on the subject, these having been carefully kept from him by his father, lest they should divert him from his literary pursuits.

PASQUIN, a mutilated statue at Rome, in a corner of the palace of the Ursini; it takes its name from a cobbler of that city, called Pasquin, famous for his sneers and gibes, and who diverted himself with passing his jokes on all the people who went through that street.

PASS, or **PASSPORT**, a permission granted by any state to navigate in some particular sea without hinderance or molestation. It contains the name of the vessel and that of her master, together with her tonnage, and the number of her crew, certifying that she belongs to the subjects of a particular state, and requiring all persons at peace with that state to suffer her to proceed in her voyage without interruption.

PASS, a strait, difficult, and narrow passage, which shuts up the entrance into a country. The first care of the general of an army is, to seize the passes of the country into which he would carry the war, to fortify them, and take care that they are well guarded.

Pass, or **Passade**, in Fencing, an advance or leap forward upon an enemy. Of these there are several kinds; as, *passes* within, above, beneath, to the right, the left, and *passes* under the line, &c.

Pass Parole, a command given, which passes from mouth to mouth along the line of a regiment or army.

PASSAGE, or **Passo**, any phrase, or short portion of any air, or other composition. Every member of a strain or movement is a passage.

PASSAGE BOAT, a small vessel, employed in carrying persons or luggage from one port to another.

PASSAGE, *Birds of*. See **MIGRATION** and **ORNITHOLOGY**.

PASSAGIO, (Italian,) a succession of sounds so connected in their melody and expression, as to form a member or phrase in the composition.

PASSANT, in Heraldry, a term applied to a lion or other animal, in a shield, appearing to walk leisurely.

PASSAREE, a rope to confine the tacks towards the ship when she is going large in light breezes; it is, however, very rarely used.

PASSERES, in Natural History, the sixth order of birds according to the Linnæan system. They live chiefly in trees and hedges, are monogamous, vocal, and feed the young by thrusting the food down their throats.

PASSIFLORA, or **PASSION FLOWER**, a genus of plants belonging to the gynandria class, and in the natural method ranking under the 34th order, cucurbitaceæ.

PASSPORT, or **Pass**, a license or writing obtained from a prince or governor, granting liberty and safe-conduct to pass through his territories without molestation. Passport also signifies a license obtained for importing contraband goods, or for exporting and importing merchandise without paying the duties; these last licenses are always given to ambassadors and other public ministers for their baggage, equipage, &c.

PASTE. Imitations of gems are so called. Such substances are selected, to be fused together, as will produce an artificial glass, resembling in appearance the gem intended, and sufficiently hard and beautiful. The art has been brought to such perfection, that it requires a very close inspection of the skillful to be able to distinguish the real from the apparent. The art is much encouraged, not only by the vain, who are unable even to procure real gems, but also to replace for a time the diamonds of such persons as find it convenient to procure a temporary loan by pledging their jewels. Silica, borax, red oxide of lead, potash, and sometimes arsenic, are the base of all artificial stones. The fusion should be kept up moderately twenty-four hours together. We shall close this article with the following

Description of a Furnace constructed for Lord Bute by Mr. Peter Woulfe, for Experiments on Pastes, or Coloured Glasses.—The furnace, of which we have given a vertical, and horizontal section, (in plate *Lord Bute's Furnace*, &c.) is a copy of a drawing in a manuscript book of experiments and memorandums, in the hand-writing of Mr. Woulfe, (the contriver of the apparatus that goes by his name,) who gives the following description of it:—In this furnace, which is drawn on a scale of one-sixteenth of an inch to the inch, two hundred experiments on the formation of coloured pastes or glasses may be made at once. In the drawing, where the same letters occur in different sections, they refer to the same parts of the furnace. Fig. A, is a vertical section of the furnace; a, the ash pit, or air hole, which opens on the outside of the house, and has an iron door with a register in it; b, the grate and fireplace; c, the first chamber, for one circular row of large crucibles, placed on the floor c; d, the second chamber or floor, for two rows of crucibles; e, the third chamber, for two rows of crucibles; f, the fourth chamber, for tests or crucibles; g, h, i, k, doors opening into the four chambers, each of which has three doors: see the same letters in the horizontal sections BCDE. l, the door of the furnace. m m m m m, the flue in the building, which rises three stories high. B is a horizontal section of the first chamber; c, the floor or circular shelf on which the crucibles are placed; g g g, three doors or openings. C, a horizontal section of the second chamber; d, the floor or shelf; k k k, the doors. Fig. D, a section of the third chamber; shewing its shelf or floor e, and its three doors i i i. Fig. E, section of the fourth or upper chamber, in which f is the floor, and k k k the three

doors for putting in, or taking out, tests or crucibles. A shilling put into a red-hot test in this chamber, melted in one minute and a half. The front of the furnace is at the side answering to the middlemost of the three doors on the respective floors, viz. the side marked *lg k ik*, in fig. A. The best way of understanding the use of such things, is by visiting the workshops of artists employed in the manufacture of artificial gems.

PASTEBOARD, a kind of thick paper, formed of several sheets of paper pasted together. The chief use of pasteboard is in binding books, making letter-cases, &c. See PAPER.

PASTORAL, in general, something that relates to shepherds; hence we say, pastoral life, manners, poetry, &c. The origin of poetry is ascribed to that age which succeeded the creation of the world; and as the keeping of flocks seem to have been the first employment of mankind, the most ancient sort of poetry was probably pastoral.

PASTURE, is generally any place where cattle may feed, and in law, is mostly applied to a common of pasture, or right of feeding cattle on certain waste lands.

PATEE, or **PATTEE**, in Heraldry, a cross, small in the centre, and widening to the extremes, which are very broad.

PATELLA, or **LIMPET**, a genus of insects belonging to the order vermes testacea. They are always attached to some hard body. Their summit is sometimes acute, sometimes obtuse, flattened, turned back, or perforated.

PATENT, in general, denotes something that stands open or expanded; thus, a leaf is said to be patent when it stands almost at right angles with the stalk.

PATENT, or *Letters Patent*, are writings sealed with the great seal of England, by which a man is authorized to do, or to enjoy, any thing which of himself he could not. They are so called on account of their form, being open, with their seal affixed, ready to be exhibited for the confirmation of the authority delegated by them. Letters patent, for new inventions, are obtained by petition to the crown: they go through many offices, and are liable to opposition, on account of the want of novelty, &c. and if obtained, and it can be proved that the invention was not new, or had been made public previously to the granting the patent, they may be set aside. A patent at the lowest cost, and when no opposition is given to it, will, for fees of office, specification, &c. cost for the three branches of the United Kingdom, three hundred pounds.

PATHOLOGY, that part of medicine which explains the symptoms of diseases.

PATROL, in war, a round or march made by the guards, or watch, in the night-time, to observe what passes in the streets, and to secure the peace and tranquillity of a city or camp. The patrol generally consists of a body of five or six men, detached from a body on guard, and commanded by a sergeant.

PATRON, in the canon and common law, is a person, who having the advowson of a parsonage, vicarage, or the like spiritual promotion, belonging to his manor, has, on that account, the gift and disposition of the benefice, and may present to it whenever it becomes vacant.

PATRONYMIC, among Grammarians, is applied to such names of men and women as are derived from those of parents or ancestors.

PAUL, a short bar of wood or iron, fixed close to the capstan or windlass of a ship, to prevent those engines from rolling back or giving way, when they are charged with any great effort. *Paul Bits*, are pieces of timber fixed perpendicularly before the windlass, near the middle of it, and serving as supports to the pauls which are pinned into them.

PAULICIANS, Christians of the seventh century, disciples of one Constantine, a native of Armenia, and a favourer of the errors of Manes.

PAUPER. A person receiving public charity.

PAUSE, in Music, a mark or character, consisting of a curve drawn over a dot, and signifying that the note or the rest, over which it is placed, is to be continued beyond the regular time.

PAVEMENT, a layer of stone or other matter, serving to cover and strengthen the ground of divers places for the more commodious walking on. In London the pavement for coach ways is chiefly a kind of granite from Scotland; and on the footpath Yorkshire paving is used; the kirbstone is usually of

Scotch granite; courts, stables, kitchens, halls, churches, &c. are paved usually with tiles, bricks, flags, or fire stones; and sometimes with a kind of freestone and rag stone. In France, the public roads, streets, courts, &c. are paved with gres, a kind of freestone. In Venice, the streets, &c. are paved with brick; churches sometimes with marble, and sometimes with Mosiac work. In Amsterdam, and the chief cities of Holland, they call their brick pavement, the burgomasters' pavement, to distinguish it from the stone or flint pavement, which is usually in the middle of the street, serving for the passage of their horses, carts, coaches, and other carriages; the brick borders being designed for the passage of people on foot.

PAVO, the *Peacock*, in Ornithology, a genus belonging to the order of gallinæ. The head is covered with feathers which bend backwards; the feathers of the tail are very long, and beautifully variegated with eyes of different colours. Latham enumerates eight species. These birds feed almost solely on insects and grain. They prefer elevated situations for roosting, choosing the tops of houses and the highest trees for this purpose. They were considered as luxuries for the table by the Romans, and the young ones are now regarded as a delicacy. Their voice is harsh and dissonant, and in perfect contrast to that beauty exhibited by their plumage, which, in the language of Buffon, "seems to combine all that delights the eye in the soft and delicate tints of the finest flowers, all that dazzles in the sparkling lustre of the gem, and all that astonishes in the grand display of the rainbow."

PAVO ET INDUS, the *Peacock and Indian*, a constellation situated on the Antarctic circle, contains twenty-six stars, of which one is of the 2nd magnitude, three of the 3d, and four of the 4th. The brilliant α is made of the eye of the proud bird. It has 20 ho. 11' 30" right ascension in Time, (*Ann. Var.* 4th. 64,) and 57° 17' 41" S. declination, (*Ann. Var.* 10th. 72.)

PAWN, a pledge lodged for the security of the payment of a sum of money borrowed.

PAY, To, as a naval term, implies to daub or anoint the surface of any body, in order to preserve it from the injuries of the water, weather, &c. *To Pay a Vessel's Bottom*, to cover it with a composition of tallow, sulphur, rosin, &c.

PAYING OFF, the movement by which a ship's head falls to leeward, particularly when, by neglect of the helmsman, she had inclined to windward of her course, so as to make the head sails shiver in the wind. *Paying off*, also implies the payment of the ship's officers and crew, and the discharge of the ship from actual service. *Paying out*, or *Paying away*, the act of slackening a cable or other rope, so as to let it run out of the vessel.

PAYMENT, is the consideration or purchase-money for goods, and may be made by the buyer giving to the seller the price agreed upon, either by bill or note, or by money.

PEACE, in Law, signifies a quiet and harmless behavior towards the king and his people.

PEACE, JUSTICES OF. See JUSTICE OF THE PEACE.

PEACH. This rich and delicious fruit is highly and deservedly esteemed at table, as an article in our deserts; and when ripe and fresh, is grateful and wholesome, seldom disagreeing with the stomach, unless this organ be not in a healthy state, or the fruit has been eaten to excess. When preserved in wine, brandy, or sugar, it loses its good properties. The kernels yield a salubrious bitter. The flowers, which are very beautiful, and appear only in the spring, emit an agreeable odour, have a bitterish taste, and, including the calyx as well as the corolla, are used for medical purposes. The leaves are occasionally employed in cookery, but they ought not to be used without great caution, on account of their injurious properties. There are many varieties of the peach, some of which are much more esteemed than others. The mode in which the trees are usually propagated is by a process usually termed budding, or grafting upon the stock of some other tree; and by this process those of any favourite kind may be exactly obtained.

PEAK, a name given to the upper corner of those sails which are extended by a gaff, or by a yard which crosses the mast obliquely, as the mizzen yard of a ship, the main yard of a by-lander, &c. The upper extremity of these yards and gaffs are also denominated the peak.

PEAK Haliards, are the ropes or tackles by which the outer end of a gaff is hoisted, as opposed to the throat haliards.

PEAR, *The Common*, is a well-known garden fruit, derived from an English stock, (the wild pear tree,) which grows in hedges and thickets in Somersetshire and Sussex. It would be an endless task to describe the different known varieties of the cultivated pear. Some of these are very large, and others extremely small; some have a rich and luscious flavour, and others, as the iron pear, are so hard and disagreeable to the taste, as to be absolutely unfit to eat. Pears are chiefly used in desserts; and one or two of the kinds are stewed with sugar, baked, or preserved in syrup. The fermented juice of pears is called perry, and is prepared nearly in the same manner as that of apples is for cider. The greatest quantities of perry are made in Worcestershire and Herefordshire. The *Squash*, the *Oldfield*, and the *Barland perry*, are esteemed the best. Many of the dealers in Champagne wine are said to use perry to a great extent in the adulteration of it; and, indeed, really good perry is little inferior in flavour or quality to Champagne. Of the wood of the pear tree, which is light, smooth, compact, and of a yellowish colour, carpenters' and joiners' tools are usually made, as well as the common kinds of flat rulers, and measuring scales. It is also used for picture frames that are to be stained black. The leaves impart a yellow die, and are sometimes employed to communicate a green colour to blue cloth.

PEARLS, are a calculus or morbid concretion, formed in consequence of some external injury which the muscle or shell-fish receives that produces it, particularly from the operations of certain minute worms which occasionally bore even quite through to the animal. The pearls are formed in the inside on these places. Hence it is easy to ascertain, by the inspection of the outside only, whether a shell is likely to contain pearls. If it be quite smooth, without cavity, perforation, or callosity, it may with certainty be pronounced to contain none. If, on the contrary the shell be pierced or indented by worms, there will always be found either pearls, or the embryos of pearls. It is possible, by artificial perforation of the shells, to cause the formation of these substances. The process which has been chiefly recommended, is to drill a small hole through the shell, and to fill it up with a piece of brass wire, riveting this on the outside like the head of a nail; and the part of the wire which pierces the interior shining coat of the shell, will, it is said, become covered with a pearl. As to the value of British pearls, some have been found of size so large as to be sold for £20 each, and upwards; and £80 was once offered and refused for one of them. It is reported in Wales, that a pearl from the river Conway, which was presented to the queen of Charles the Second, was afterwards placed in the regal crown.

The Oriental PEARL Muscle to which we are indebted for nearly all the pearls of commerce, has a flattened and somewhat circular shell, about eight inches in diameter; the part near the hinge bent or transverse, and imbricated (or covered like slates on a house) with several coats, which are toothed at the edges. Some of the shells are externally of sea-green colour, others are chesnut or reddish, with white stripes or marks; and others whitish with green marks. These shells are found both in the American and Indian seas. The principal pearl fisheries are of the casts of Hindoostan and Ceylon. They usually commence about the month of March, and occupy many boats and a great number of hands. Each boat has generally twenty-one men, of whom one is the captain, who acts as pilot; ten row and assist the divers, and the remainder are divers, who go down into the sea alternately by five at a time. The king of Persia has a pear-shaped pearl so large and pure as to have been valued at £110,000 sterling. The largest round pearl that has been known, belongs to the Great Mogul, and is about two-thirds of an inch in diameter. Pearls from the fishery of Ceylon are considered more valuable in England than those from any other part of the world. The smaller kinds are called *seed* or *dust pearls*, and are of comparatively small value, being sold by the ounce, to be converted into powder.

To make Artificial PEARLS, take the blay or bleak fish, common in the Thames, scrape off the silvery scales from the belly; wash and rub these in water. Then suffer this water to settle, and a sediment will be found, of an oily consistence. A little of this is to be dropped into a hollow glass bead of a bluish tint, and shaken about so as to cover all the internal surface; after

this, the bead is filled up with melted white wax, to give it solidity and weight.

To Whiten discoloured PEARLS.—Soak them in hot water, in which some bran with a little tartar and alum have been boiled, rub them gently between the hands, which may be continued until the water grows cold, or until the object is effected, when they may be rinsed in lukewarm water, and laid on writing paper in a dark place to cool.

PEAT, is one of the most important productions of alluvial ground; it may be regarded as belonging more properly to the vegetable than to the mineral kingdom. Peat formerly covered extensive tracts in England, but is disappearing before the genius of agricultural improvement, which has no where produced more important effects than in the conversion of the black and barren peat moors of the northern counties into valuable land, covered with luxuriant herbage, and depastured by numerous flocks. It consists of wet spongy black earth, and decayed vegetables.

PEBBLES, the name of a genus of fossils, distinguished from the flints by having a variety of colours. These are defined to be stones composed of crystalline matter debased by earths of various kinds in the same species, and then subject to veins, clouds, and other variegations, usually formed by incrustation round a central nucleus, but sometimes the effect of a simple concretion; and veined like the agates, by the disposition which the motion of the fluid they were formed in gave their different coloured substances.

PECK, an English measure, the fourth part of a bushel.

PECTEN, the *Scallop*, a genus of shell fish, the characters of which are these: the animal is a tethys; the shell bivalve and unequal; the hinge toothless, having a small ovated hollow.

PECORA, in Natural History, the fifth order of the class Mammalia. There are eight genera, viz. Antelope, Bos, Camelus, Camelopardalis, Capra, Cervus, Moschus, Ovis.

PECULIAR, signifies a particular parish or church that hath jurisdiction within itself for probate of wills, &c. exempt from the ordinary, and the bishop's court. The Court of Peculiars is that which deals in certain parishes, lying in several dioceses; which parishes are exempt from the jurisdiction of the bishops of those dioceses, and are peculiarly belonging to the archbishop of Canterbury, within whose province there are fifty-seven such peculiars.

PEDESTAL, in Architecture, the lowest part of an order of columns, being that part which sustains the column, and serves as a foot on which it may stand erect.

PEDICELLARIA, a genus of insects belonging to the order vermes mollusca.

PEDICULUS, *Louse*, a genus of insects of the order aptera.

PEEK, is a term used in various senses. An anchor is said to be a-peek when the ship being about to weigh, comes over her anchor, so that the cable hangs perpendicularly between the hawse and the anchor. (See the articles **ANCHOR** and **A-PEEK**.) Also, the bringing a ship into the above position is called heaving a-peek. She is likewise said to ride a-peek when lying with her main and fore yards hoisted up, one end of her yards is brought down to the shrouds, and the other raised up on end; which is chiefly done when she lies at rest in rivers, lest other ships, falling foul of her, should break her yards. *Peek* is also used for the room in the hold, from the bitts forward to the stern. In this place men of war keep their powder, and merchantmen their victuals.

PEER, in general, signifies an equal, or one of the same rank and station; hence, in the acts of some councils, we find these words, "with the consent of our peers, bishops, abbots," &c. Afterwards the same term was applied to the vassals or tenants of the same lord, who were called peers, because they were all equal in condition, and obliged to serve and attend him in his courts; and peers in fiefs, because they all held fiefs of the same lord. The term peers is now applied to those who are impanelled in an inquest upon a person for convicting or acquitting him of any offence laid to his charge; and the reason why the jury is so called, is, because by the common law, and the custom of this kingdom, every person is to be tried by his peers, or equals; a lord by the lords, and a commoner by commoners.

Peer of the Realm, a noble lord who has a seat and vote in the house of lords, which is also called the house of peers.

These lords are called peers, because, though there is a distinction of degrees in our nobility, yet in public actions they are equal, as in their votes in parliament, and in trying any nobleman, or other person, impeached by the commons, &c. A peer is not to be put upon any inquest, even though the cause has a relation to two peers; but in trials where any peer is either plaintiff or defendant, there must be two or more knights returned on the jury. Where a peer is defendant in a court of equity, he is not to be sworn to his answer, but it may be upon his honour, as in the trial of peers; however, when a peer is to answer to interrogatories, or to make an affidavit, or is to be examined as a witness, he is to be sworn.

PEERESS, a woman who is noble by descent, creation, or marriage. If a peeress by descent or creation marries a person under the degree of nobility she still continues noble; but if she obtains that dignity only by marriage, she loses it on her afterwards marrying a commoner; yet by the courtesy of England she always retains the title of her nobility. No peeress can be arrested for debt or trespass; for though, on account of their sex, peeresses cannot sit in the house of lords, yet they enjoy the privileges of peers, and therefore all peeresses by birth are to be tried by their peers.

PEGASUS, one of the old constellations, and known as the fabled favourite of the Muses, is a paratellon of Aquarius, and the zodiacal Fishes. We think this affinity is far more symbolical of the inroad of the Scythians into Egypt in the 7th century, than of the ark of Noah, before the Christian era; though it is not to be denied that the arkite and solar worship are frequently confounded in a much more extraordinary way, than the debased and slavish Romans confounded science and folly, by the deification of Antonius, whose medals, statues, temples, city, oracles, and constellations, are well known, and still dishonour the memory of Hadrian.

PEGASUS, is also a genus of fishes, of the order nantes.

PELAGIANS, a Christian sect who appeared before the latter part of the fourth, or the beginning of the fifth century. They are said to have maintained, 1. That Adam was by nature mortal, and whether he had sinned or not would certainly have died. 2. That the consequences of Adam's sin were confined to his own person. 3. That new-born infants are in the same condition with Adam before the fall. 4. That the law qualified men for the kingdom of heaven, and was founded upon equal promises with the gospel. 5. That the general resurrection of the dead does not follow in virtue of our Saviour's resurrection. 6. That the grace of God is given according to our merits. 7. That this grace is not granted for the performance of every moral act; the liberty of the will, and information in points of duty, being sufficient, &c.

PELECANUS, the *Pelican*, in Natural History, a genus of birds, of the order anseres. There are thirty species, of which we shall notice the following: The great pelican, is sometimes of the weight of 25 pounds, and of the width, between the extreme points of the wings, of 15 feet; the skin between the sides of the upper mandible, is extremely dilatable, reaching more than half a foot down the neck, and capable of containing many quarts of water. This skin is often used by sailors for tobacco pouches, and has been occasionally converted into elegant ladies' workbags. About the Caspian and Black seas these birds are very numerous, and they are chiefly to be found in the warmer regions, inhabiting almost every country in Africa. They build in the small isles of lakes, far from the habitations of man.—The American pelican, is about the size of a goose; of this bird it is reported that it will bring large supplies of food to any disabled and diseased companion; and that the natives of the island of Assumption, by confining one near the shore, frequently induce others to make these generous presents, which are fraudulently converted to the purpose of food for the islanders.—The man-of-war bird, is small in body, but between the extremities of the wings fourteen feet in width. It is seldom seen but within the tropics, and not unfrequently is observed two hundred leagues from land. It watches the movements of fishes from a very considerable height, and pounces upon them with unfailling success, returning from its immersion with equal rapidity.—The carbo, or cormorant, nearly as large as a goose, is found in many places both of the old and the new world, and is to be met with in the northern parts of this island. These birds

are shy and crafty, but frequently eat to so great an excess as to induce a species of lethargy, in which they are caught by nets thrown over them, without their making an effort to escape. They are trained by the Chinese to fish for them. By a ring placed round their necks, they are prevented swallowing what they take, and, when their pouches are filled, they unload them, and at the command of their owners renew their divings; two will be seen combining their efforts to secure a fish too large for the management of one only. When their work is finished to the employer's satisfaction, the birds have a full allotment of the spoil, for their reward and encouragement. In Macao, also these birds are thus domesticated, taking extreme delight in the exercise, and constituting a source of very considerable profit to their owners. They were formerly trained and used in the same manner in England; and Charles I. had an officer of his household, called master of the cormorants.—The Soland goose, or gannet, weighs about seven pounds, and inhabits in great numbers the northern isles of this kingdom. It is migratory, and drawn to this country by the shoals of herrings and pilchards, whose movements it watches with the most anxious vigilance. The young birds are sold in great plenty at Edinburgh, where they are frequently introduced before dinner as a stimulus to appetite. In St. Kilda it is supposed that upwards of twenty thousand of these birds are taken annually. They constitute an important article of food to the inhabitants, who, to procure both the eggs and young ones, expose themselves to the most imminent dangers on elevated and precipitous cliffs, and in several instances have fallen victims to the hardihood with which they have pursued their researches during the breeding season.

PELECOID, or **PELECOIDES**, hatchet form, in Geometry, contained under the two inverted quadrantal arcs AB and AD, and the semicircle BCD. The area of the pelecoid is demonstrated to be equal to the square AC; and that again to the rectangle EB. It is equal to the square AC, because it wants of the square on the left hand the two segments AB and AD, which are equal to the two segments BC and CD, by which it exceeds it on the right hand.

PELICAN, in Chemistry, a kind of double glass vessel, used in distilling liquors by circulation; it consists of a cucurbit and alembic head, with two tubes bending into the cucurbit again.

PELL, DR. JOHN, an eminent English mathematician, was born at Southwick, in the county of Sussex, in 1610, and died in London in 1685, at the age of 74. He was author of numerous papers and treatises on mathematical and astronomical subjects, but none of them are now of sufficient importance to be enumerated in this place; but a complete catalogue of them may be seen in Dr. Hutton's Mathematical Dictionary.

PELLICLE, among Physicians, &c. denotes a thin film or fragment of a membrane.

PEN, a well-known instrument used in writing, the origin of which is unknown. The fountain pen is made of silver, brass, or copper, &c. and is so contrived that it will hold a considerable quantity of ink, which it discharges as the writer proceeds. The following method has been recommended for making a self-giving, or fountain pen:—The pen is made of two quills; the top one, which we shall call No. 1, and the other No. 2. When you have ready both quills like the model, take care that the top of No. 1. be made air-tight, (which we do by dropping a small piece of cobbler's wax at the bottom, and then warm it a little;) fill it nearly with ink, say about a quarter of an inch from the brim; take a small piece of cambric or muslin, (cambric answers the best,) cover the top with it so that the ink may not drop out, join both quills together, by putting No. 1. into No. 2. and the pen is ready for use. When you want to write, take the pen in your right hand, give a gentle shock on your left hand, or on a table, and the ink will run down immediately into the pen; this must be repeated every time ink is wanted. This very cheap *self-giving ink pen*, is extremely useful for reporters and persons going into the country, and also to many others, who will take delight in

making use of it. The pen should be put in a little case to carry about.

PENAL LAWS, or **STATUTES**, having been made on many occasions, to punish or deter offenders, they ought to be construed strictly, and not be extended by equity, but the words of them may be interpreted beneficially according to the intent of the legislator.

PENALTY, is a forfeiture inflicted for not complying with the regulations of certain acts of parliament; a penalty is also annexed to secure the performance of certain covenants in a deed, articles of agreement, copartnership, &c. In a bond also for payment of money, it is usual to annex a penalty in double the amount of the obligation.

PENANCE, in our Canon Law, is an ecclesiastical punishment, chiefly adjudged to the sin of fornication.

PENCIL, an instrument used by painters for laying on their colours. Pencils are of various kinds, and made of various materials; the larger sorts are made of boar's bristles, the thick ends of which are bound to a stick, large or small according to the uses they are designed for; these, when large, are called brushes. The finer sorts of pencils are made of camels', badgers', and squirrels' hair, and of the down of swans; these are tied at the upper end with a piece of strong thread, and enclosed in the barrel of a quill. All good pencils, on being drawn between the lips, come to a fine point.

PENCIL, Black Lead. The common trash are made of black lead in powder, stirred in melted sulphur, and poured into the pencil-case, which is itself made of cedar; but good pencils are made of solid black lead glued on the cedar, and properly covered and finished. You may easily know by holding a pencil to the flame of a candle whether it be of the former or latter sort. The sulphur in the former will ignite and throw out a smell; black lead does neither.

PENCIL of Rays, in Optics, denotes a number of rays diverging from some luminous point, which, after falling upon and passing through a lens, converge again on entering the eye.

PENDANT, an ornament hanging at the ear, frequently consisting of diamonds, pearls, and other precious stones.

PENDANT, or *Pennant*, a sort of long narrow banner displayed from the mast-head of a ship of war, and usually terminating in two ends or points, called the swallow's-tail. It denotes that a vessel is in actual service.

Broad PENDANT, is a kind of flag terminating in one or two points, used to distinguish the chief of a squadron.

PENDANT, is also a short piece of rope, fixed on each side under the shrouds, upon the heads of the main and fore masts, from which it depends as low as the cat-harpings, having an iron thimble spliced into an eye at the lower end, to receive the books of the main and fore tackles. There are, besides, many other pendants of this latter kind, which are generally single or double ropes, to whose lower extremity is attached a block or tackle; such are the fish pendant, stay-tackle pendant, yard-tackle pendant, reef-tackle pendant, &c. all of which are employed to transmit the efforts of their respective tackles to some distant object.

Rudder PENDANT, is a strong rope made fast by means of a chain to a rudder. Its use is to prevent the loss of the rudder, if accidentally unshipped or disengaged from the gudgeons.

PENDULUM, in Mechanics, denotes any heavy body so suspended that it may vibrate, or swing backwards and forwards, about some fixed point, by the action of gravity. The vibrations of a pendulum are called its *oscillations*, the time of each being counted from the time of its descent from the highest point on one side, till it attains the highest point on the opposite side. A pendulum, therefore, is a heavy body B, suspended upon and moving about some fixed point at A as a centre. Here the point A is called the *centre of motion*, or of *suspension*, and the line P Q parallel to the horizon, the *axis of oscillation*, and that point in the body B, into which, if all the matter of the body was condensed, so as still to perform its oscillations in the same time, is called the *centre of oscillation*; and

the distance of this point from the point of suspension, is accounted the *length* of the pendulum. See *Centre of Oscillation*.—Pendulums receive particular denominations, according to the materials of which they are composed, or the purposes they are intended to answer; for an account of which, see the subsequent part of this article; we shall here confine our remarks to the theory of the simple pendulum.

Simple PENDULUM, theoretically considered, is a single weight attached to a string supposed to be devoid of gravity, and oscillating freely, without resistance either from friction or the air.

Properties of the Simple Pendulum thus constituted, and vibrating in small circular Arcs.—1. The vibrations of the same pendulum, or of different pendulums of the same length, and in the same place, in very small arcs of circles, are always performed in the same time. 2. The velocity of the bob, in the lowest point of the arc, will be very nearly as the length of the chord of the arc which it describes in its descent. 3. The times of vibration of different pendulums are, to each other, as the square roots of their length. Or their lengths are as the squares of the number of vibrations performed in the same time. 4. On the supposition above made, viz. that there is neither friction nor resistance opposed to the motion of the pendulum, that motion would be perpetual, that is, the force which it acquires in its descent would carry it up to the same height on the opposite side, which would be again repeated in its descent, and thus it would continue to oscillate constantly through the same arc, and consequently its vibrations uniform and perpetual. But as it is impossible to divest it of these two retarding forces, it is obvious, as well from theory as practice, that without the application of some external force, the vibrations will be shortened in every ascent, and the motion of the pendulum ultimately cease. 5. The time of vibration in a circular arc of any sensible magnitude, is expressed by the following formulæ:

$$\text{time} = p \sqrt{\frac{d}{4g}} \times \left\{ 1 + \frac{1^2 a^2}{2^2 d} + \frac{1^2 \cdot 3^2 a^2}{2^2 \cdot 4^2 d^2} + \frac{1^2 \cdot 3^2 \cdot 5^2 a^2}{2^2 \cdot 4^2 \cdot 6^2 d^3} + \&c. \right\}$$

Where $d = 2AB$, or twice the length of the pendulum, $a = CB$ the versed sine of half the arc of vibration, $g = 16 \frac{1}{2}$ half the force of gravity, and $p = 3.1416$ the circumference of a circle whose diameter is 1. 6. When a is very small, as in the preceding cases, then writing $2l$ instead of d , and omitting all the terms in the series beyond the second as being inconsiderable, we shall have

$$\text{time} = p \sqrt{\frac{l}{2g}} \times \left(1 + \frac{a}{g l} \right) = \frac{p}{g l} \sqrt{\frac{l}{2g}} \times (8l + a.)$$

7. Or instead of using the versed sine of the half arc, we introduce the degrees in that arc, the expression becomes

$$\text{time} = p \sqrt{\frac{l}{2g}} \times \left(1 + \frac{d^2}{6234} \right).$$

Properties of Pendulums vibrating in cycloidal Arcs.—1. It is a property of the cycloid that its evolute is a cycloid, similar and equal to the former. If therefore a pendulum be suspended from C, the point of concurrence of two equal inverted semicycloidal cheeks, and be made to vibrate between them, the bob will describe the cycloidal arc HAK, and the properties of a pendulum thus suspended are:

2. The time of oscillation in all arcs, whether great or small, are performed in the same time. 3. The time of vibration in any arc, is to the time in which a heavy body would fall by the force of gravity through half the length of the pendulum; as the circumference of a circle is to its diameter. Now by the laws of falling bodies

$\sqrt{\frac{l}{2g}}$ = the time of a body falling through $\frac{1}{2} l$, or $\frac{1}{2} CA$; therefore putting $p = 3.1416$, the circumference of a circle whose diameter is 1, we have as $1^2 : p :: \sqrt{\frac{l}{2g}} : p \sqrt{\frac{l}{2g}}$ the

time of vibration of a pendulum whose length is l . 4. In this formula, as well as in those given above, the time of vibration depends not only on the length of the pendulum, but also on the value of g , which differ in different latitudes; and consequently the lengths of the pendulum designed to vibrate any proposed number of times in a second, in any place, must be regulated by the value of g , or by the force of gravity at that place. 5. The value of g in the latitude of London is $16\frac{1}{2}$ feet, or 193 inches, which being substituted for g in the expression $p\sqrt{\frac{l}{2g}}$, gives $l = 39\cdot11$, or $39\frac{1}{2}$ inches for the length of the

seconds' pendulum, which is extremely near the true length as determined from accurate experiments, which shew it to be about $39\frac{1}{2}$ inches. 6. From the above formula may also be found the force of gravity in any particular place, the length of the seconds' pendulum being previously found from experiment; for, squaring the above, we have $\frac{p^2 l}{2g} = 1$, or $g = \frac{1}{2} p^2 l$,

the descent of a heavy body in one second, in terms of the length of the seconds' pendulum; and this is a much more accurate method of finding the force of gravity, than any other which depends simply on experiments. 7. In the simple pendulum, vibrating in very small arcs, we found that the time of

one vibration was nearly $= p\sqrt{\frac{l}{2g}} \times \left(1 + \frac{a}{8l}\right)$, where a is the versed sine of half the arc of vibration, whereas in a cycloid the time is simply $p = \sqrt{\frac{l}{2g}}$, and therefore the time lost each

vibration in the former case is $\frac{a p}{8l} \times \sqrt{\frac{l}{2g}}$, or, estimating by

the degrees of the arc, it is $\frac{D^2 p}{62524} \times \sqrt{\frac{l}{2g}}$; and hence we may

compute how much the pendulum must be shortened in the former case to make its vibrations correspond with one vibrating as in the latter case. 8. And since the length of the pendulum varies in different latitudes in consequence of the variation in the force of gravity, on this principle is computed the following Table, which shows the length of the seconds' pendulum for every five degrees of latitude from the equator to the pole.

Deg. of Latitude.	Length of Pendulum.	Deg. of Latitude.	Length of Pendulum.
0	39·027	50	39·126
5	39·029	55	39·142
10	39·032	60	39·158
15	39·036	65	39·178

35	39·084	85	39·195
40	39·097	90	39·197
45	39·111		

The foregoing laws, &c. of the motion of pendulums, cannot strictly hold good, unless the thread that sustains the ball be void of weight, and the gravity of the whole ball be collected into a point. In practice, therefore, a very fine thread, and a small ball, but of a very heavy matter, are to be used. But a thick thread and a bulky ball disturb the motion very much; for in that case, the simple pendulum becomes a compound one; it being much the same thing, as if several weights were applied to the same inflexible rod in several places.

Having said thus much with regard to simple pendulums, it remains only to offer a few remarks on the nature of compound pendulums, as applied to clocks and other machines where uni-

form motion is required. We have seen above, that pendulums in different latitudes require to be of different lengths, in order that they may perform their vibrations in the same time; but besides this, there is another irregularity in the motion of a pendulum in the same place, arising from the different degrees of temperature. Heat expanding and cold contracting the rod of the pendulum, a certain small variation must necessarily follow in the time of its vibration; to remedy which defect various methods have been invented for constructing what are commonly called *compensation pendulums*, or such as shall always preserve the same distance between the centre of oscillation and the point of suspension; but of these we can only describe one or two of the most approved construction.

Compound or Compensation PENDULUMS, have received different denominations from their form and materials, as the *gridiron pendulum*, *mercurial pendulum*, *lever pendulum*, &c.

Gridiron PENDULUM. Instead of one rod, this pendulum is composed of any convenient odd number of rods, as five, seven, or nine; being so connected, that the effect of one set of them counteracts that of the other set; and therefore, if they are properly adjusted to each other, the centres of suspension and oscillation will always be equidistant. The two outer rods, A B, C D, which are of steel, are fastened to the cross pieces A C, B D, by means of pins. The next two rods, E F, G H, are of brass, and are fastened to the lower bar B D, and to the second upper bar E G. The two following rods are of steel, and are fastened to the cross bars E G and I K. The two rods adjacent to the central rod being of brass, are fastened to the cross pieces I K and L M; and the central rod, to which the ball of the pendulum is attached, is suspended from the cross

piece L M, and passes freely through a perforation in each of the cross bars I K, B D. From this disposition of the rods, it is evident, that by the expansion of the extreme rods, the cross piece B D, and the two rods attached to it, will descend; but since these rods are expanded by the same heat, the cross piece E G will consequently be raised, and therefore also the two next rods; but because these rods are also expanded, the cross bar I K will descend; and by the expansion of the two next rods, the piece L M, will be raised a quantity sufficient to counteract the expansion of the central rod. Whence it is obvious, that the effect of the steel rod is to increase the length of the pendulum in hot weather, and to diminish it in cold weather, and that the brass rods have a contrary effect upon the pendulum. The effect of the brass rods must, however, be equivalent not only to that of the steel rods, but also to the part above the frame and spring which connects it with the cock, and to that part between the lower part of the frame and centre of the ball.

Another excellent contrivance, for the same purpose, is described in a French author on clock-making. It was used in the north of England by an ingenious artist, about fifty years ago. This invention is as follows:—A bar of the same metal with the rod of the pendulum, and of the same dimensions, is placed against the back part of the clock-case; from the top of this a part projects, to which the upper part of the pendulum is connected by two fine pliable chains or silken strings, which just below pass between two plates of brass, whose lower edges always terminate the length of the pendulum at the upper end. These plates are supported on a pedestal, fixed to the back of the case. The bar rests upon an immoveable base, at the lower part of the case; and is inserted into a groove, by which means it is always retained in the same position. From this con-

struction, it is evident that the extension or contraction of this bar, and of the rod of the pendulum, will be equal, and in contrary directions. For, suppose the rod of the pendulum be expanded any given quantity by heat, then, as the lower end of the bar rests upon a fixed point, the bar will be expanded upwards, and raise the upper end of the pendulum just as much as its length was increased; and hence its length below the plates will be the same as before. Of this pendulum, somewhat improved by Mr. Crosthwaite, watch and clock maker, Dublin, we have the following description. "A and B are two rods of steel forged out of the same bar, at the same time, of the same temper, and in every respectsimilar. On the top of B is formed a gibbet C; this rod is firmly supported by a steel bracket D, fixed on a large piece of marble E, firmly set into the wall F, and having liberty to move freely upwards, between

cross staples of brass 1, 2, 3, 4, which touch only in a point in front and rear, (the staples having been carefully formed for that purpose,) to the other rod is firmly fixed by its centre the lens G, of twenty-four pounds weight, although it should, in strictness, be a little below it. This pendulum is suspended by a short steel spring on the gibbet at C; all which is entirely independent of the clock. To the back of the clock-plate, I, are firmly screwed two cheeks nearly cycloidal at K, exactly in a line with the centre of the verge L. The maintaining power is applied by a cylindrical steel stud, in the usual way of regulators, at M. Now, it is very evident, that any expansion or contraction that takes place in either of these exactly similar rods, is instantly counteracted by the other; whereas in all compensation pendulums, composed of different materials, however just the calculation may seem to be, that can never be the case, as not only different metals, but also different bars of the same metal, that are not manufactured at the same time, and exactly in the same manner, are found, by a good pyrometer, to differ materially in their degrees of expansion and contraction, a very small change affecting one and not the other."

The expansion and contraction of straight-grained fir wood lengthwise, by change of temperature, is so small, that it is found to make very good pendulum rods. The wood called sapa-dillo is said to be better. There is good reason to believe, that the previous baking, varnishing, gilding, or soaking of these woods in any melted matter, only tends to impair the property that renders them valuable. They should be simply rubbed on the outer side with wax and a cloth. In pendulums of this construction, the error is greatly diminished, but not taken away. As pendulums are expanded by heat, and contracted by cold, and the time of their vibration is thereby affected, various expedients have been attempted, to remedy this defect, the most important of which is the gridiron pendulum.

The *Mercurial PENDULUM* was the invention of the ingenious Mr. Graham, in consequence of several experiments relating to the materials of which a pendulum might be formed, in 1715. Its rod is made of brass, and branches towards its lower end, so as to embrace a cylindrical glass vessel 13 or 14 inches long, and about 2 inches in diameter; which being filled about 12 inches deep with mercury, forms the weight or ball of the pendulum. If upon trial the expansion of the rod be found too great for that of the mercury, more mercury must be poured into the vessel; if the expansion of the mercury exceeds that of the rod, so as to occasion the clock to gain with an increase of temperature, some mercury must be taken out of the vessel, in order to shorten the column. And thus may the expansion and contraction of the quicksilver in the glass be made exactly to balance the expansion and contraction of the pendulum rod, and thus preserve the distance between the centre of oscillation and the point of suspension invariably the same.

Reid's *Compensation PENDULUM*, is a recent invention of Adam Reid of Woolwich, the construction of which is as follows:—A N is a rod of wire, and Z Z a hollow tube of zinc, which slips on the wire, being stopped from falling off by a nut N, on which it rests; and on the upper part of this cylinder of zinc rests the heavy ball B; now the length of the tube Z Z being so adjusted to the length of the rod A N, that the expansions of the two bodies shall be equal with equal degrees of temperature; that is, by making the length of the zinc tube to that of the wire, as the expansion of wire is to that of zinc, it is obvious that the ball B will in all cases preserve the same distance from A; for just so much as it would descend by the expansion of the wire downwards, so much will it ascend by the expansion of the zinc upwards, and consequently its vibrations will in all temperatures be performed in equal times.

On the method of determining the Figure of the Earth by the Pendulum.—The method of determining the figure of the earth by means of the Pendulum, depends upon the variation of gravity at the earth's surface. This subtle and pervading power tends to communicate to bodies exposed to its influence equal velocities in equal times. One of the modifications of this action is the oscillation of the pendulum, which is of longer or shorter duration, according to the energy of the attractive force, and the square root of the length of the pendulum. If the earth were an exact sphere, destitute of the motion of rotation, and possessing the same density throughout its whole mass, the force of gravity, by which bodies at its surface are drawn towards the centre, would be uniform, and invariable in every latitude. But the elliptical form of the earth destroys this uniformity, and causes the attractive force at the poles to preponderate over that at the equator. This inequality in the force, by which bodies at the surface of the earth retain their positions, is augmented by the diurnal rotation, which, by its centrifugal tendency, impresses a greater disposition on bodies to recede from the centre of the earth at the equator than at the poles, where its effects cease to be felt. By the joint operation of these two causes, one of which acts with a force proportional to the square of the sine of the latitude, a sensible difference ought to be observed in the velocity acquired by heavy bodies, in falling through the same space, as we advance from the equator to the poles. An important relation between the time of the vibration of a pendulum, and that of the descent of a heavy body, according to which the lengths of pendulums, vibrating synchronously, are directly as the force of gravity, enables us to submit this conclusion to the test of experiment. Newton long ago demonstrated, that if the earth were perfectly homogeneous, the same fraction, viz. $\frac{1}{256}$, would express both the compression of the terrestrial ellipsoid, and the increase of gravity from the equator to the poles. This conclusion, which was deduced from the supposition of an uniform density, was afterwards modified, with singular address, by Clairaut, who shewed, that the two fractions expressing the compression, and the increase of gravity, though not exactly equal, must always together amount to $\frac{1}{256}$. Assuming the compression, therefore, to be equal to $\frac{1}{256}$, the increase of gravity from the equator to the poles, or the indication of that increase, as given by the length of the pendulum, should be $\frac{1}{256} - \frac{1}{256}$, or $\frac{1}{256}$ nearly. The correctness of this conclusion, if not completely established, is, at least, to a certain extent, confirmed, by the experiments which have been made with the pendulum in different latitudes. La Place having selected fifteen of the best of these observations, and applied to them the necessary corrections, on account of the resistance of the air, difference of temperature, and elevation above the level of the sea, deduced the following results, in which the length of the pendulum at Paris is considered to be unity.

The following results indicate obviously an increase of the force of gravity from the equator towards the poles. La Place has shewn that, in whatever way they are combined, it is impossible to avoid an error of less than .00018, on the hypothesis of the variation of gravity at the surface of the earth increasing as the squares of the sines of the latitude from the equator to the poles.

The expression for the ellipticity, which connects best the different equations of condition, is $\frac{335}{78}$, and this is a result which accords in a very remarkable manner with the compression deduced from the measures of the French mathematicians in France, and at the equator. It may be inferred from these experiments with the pendulum, that the compression of the earth is greater than is compatible with the supposition of an uniform density. The same anomalies, too, which are discernible in the measurement of a degree of the meridian, and which are undoubtedly owing to the dissimilar structure of the globe, may be traced in the results of these experiments. The beautiful property of the pendulum, first discovered by Huygens, that the centre of oscillation and the point of suspension, are interchangeable with each other, and which has been so happily applied by Captain Kater, to determine the length of the seconds' pendulum, renders this mechanical contrivance infinitely better fitted to ascertain the true figure of the earth, than the complicated methods which were formerly employed for the same purpose. The facility with which the observations may be made, and the certainty of the results with which they are attended, may be expected to furnish much interesting information, not only with respect to the general form of the globe, but also with respect to its structure and composition in particular situations.

PENELOPE, a genus of birds, of which there are four species, of the order gallinæ.

PENETRABILITY, the capability of being penetrated.

PENETRALE, a sacred room or chapel in private houses, which was set apart for the worship of the household gods among the old Romans. The *penetralia* of the temples contained the images of the gods, and were sacred to the performance of particular rites.

PENETRATION, is used principally to denote the forcible entry of one solid body within another by means of a projectile motion, communicated to the former, which enables it to displace those parts of the latter with which it comes in contact. Or, the penetration may be otherwise produced by the action of some percussive force acting upon one of the bodies when in contact with the other; these two cases, however, differ rather in circumstances than in principle, and therefore in the slight sketch we shall give of this subject, we shall consider the penetrating body to be projected with a certain velocity, and impinging upon the fixed body in a direction perpendicular to its surface. This is a subject of considerable importance in military and naval gunnery, and has been accordingly treated of by different writers on these subjects; Dr. Hutton in particular has made several experiments on different substances, and with different charges of powder, and different weight of shot, in order to procure data from which the penetration in other cases may be determined. The mean results of the most accurate of his experiments, as given in vol. iii. of his *Tracts*, are stated in the next column:

Velocity in feet.	Substances.	Diam. of iron shot in inches.	Penetration.
1600	Elm	1·96	20 inch.
1200	Ditto	1·96	15
1500	Ditto	2·78	30
1060	Ditto	2·78	16
1200	Oak	5·04	34
1300	Earth	5·55	15 feet.

In these experiments the gun was placed so near the object, that the initial velocity of the ball was not changed, and the penetration was made lengthways of the timber, which in the first four cases was sound elm, cut off near the root of the tree; the other two experiments were made by Robins, and given by that author, with some others, in his tract on Gunnery. The first two experiments, with the velocity 1600 and 1200 feet, give 20 and 15 inches for the penetration, being precisely in the ratio of the two velocities; but this ratio does not obtain in the next two experiments; in fact, it is pretty obvious that this cannot be the case, unless the resisting force of the wood was uniformly the same throughout, which cannot be; its density about the penetrating body increasing every instant, in consequence of the parts forced in by the ball, which accounts for the results as deduced by Dr. Hutton on this hypothesis not agreeing with each other. It is ascertained by a very rigid formula, that the depth penetrated is as the density and diameter of the ball, and the square of the velocity, divided by the strength, or resisting force, of the matter or obstacle; so that if equal balls be discharged against the obstacle, the depths will be as the squares of the velocities.

PENGUIN, in Ornithology, a genus of birds, of the order of anseres, of which there are twelve species.

PENINSULA, is a tract of land joined to the continent by a narrow neck called isthmus.

PENITENCE, *Religious Orders* of, consisting of either converted debauchees and reformed prostitutes, or of persons who devote themselves to the office of reclaiming them; as, the *Order of Penitence of St. Magdalen*, founded in 1272, &c. Since 1616, none have been admitted but maids, although the congregations still retain their ancient name.

PENNATULA, or **SEA PEN**, a genus of zoophyte, which, though it swims about freely in the sea, approaches near to the gorgonia. This genus has a bone along the middle of the inside, which is its chief support; and this bone receives the supply of its osseous matter by the same polype-mouths that furnish it with nourishment. Linneus reckons seven species.

PENNY, an English copper coin, the 12th part of a shilling.

PENNYWEIGHT, the 20th part of an ounce Troy. This weight derived its name from being exactly the weight of an ancient English silver penny.

PENSTOCK, is a sluice or floodgate, serving to retain, or let go at pleasure, the water of a millpond. The following is a description of a pentrough and stock for equalizing the water falling on water wheels, by George Quayle, Esq. To insure a regular supply of water on the wheel, and to obviate the inconveniences arising from the usual mode of delivering it from the bottom of the pentrough, this method is devised, of regulating the quantity delivered by a float, and taking the whole of the water from the surface. Section of the pentrough:—A, fig. 1, the entrance of the water; B, the float, having a circular aperture in the centre; in which is suspended C, a cylinder, running down in the case E below the bottom of the pentrough. This is made water-tight at the bottom of the pentrough at F, by a leather collar placed between the two plates, and screwed down to the bottom. The cylinder is secured to the float, so as to follow its rise and fall; and the water is admitted into it through the opening in its side, and there, passing through the box or case E, rises and issues at G on the wheel. By this means, a uniform quantity of water is obtained at G; which quantity can be increased or diminished by the assistance of a small rack and pinion attached to the cylinder, which will raise or depress the cylinder above or under the water-line of the float; and, by raising it up to the top, it stops the water entirely, and answers the purpose of the common shuttle. This pinion is turned by the handle H, similar to a winch handle, and is secured from running down by a ratchet wheel at the opposite end of the pinion axis. K and L are two upright rods, to preserve the perpendicular rise and sinking of the float,

running through the float, and secured at the top by brackets from the sides. *M*, a board let down across the pentrough, nearly to the bottom, to prevent the horizontal impulse of the

water from disturbing the float. Fig. 2, a transverse section, shewing the mode of fixing the rack and pinion, and their supports, on the float. The rack is inserted into a piece of metal running across the cylinder near the top. That the water may pass more freely when nearly exhausted, the bottom of the cylinder is not a plane, but is cut away so as to leave two feet, as at *C*, Fig. 1. The float is also kept from lying on the pentrough bottom by four small feet, so that the water gets under it regularly from the first. Fig. 3, an enlarged view of the cylinder, showing the rack and ratchet wheel, with the click, and one of the openings on the side of the cylinder; the winch or handle being on the opposite side, and the pinion, by which the rack is raised, being enclosed in a box between them. See SLUICE.

PENTAGON, (from *five* and *angle*.) in Geometry, is a figure of five angles, and consequently also of five sides, and when these are both equal, it is called a regular pentagon, but otherwise it is irregular. The angle at the centre of a pentagon is 72° , and the angle of its sides 144° . The area of a pentagon, whose side is one, is 1.7204774 ; consequently, when the side is s , the area $= s^2 \times 1.7204774$.

To inscribe a Pentagon in a given Circle.

—Draw the diameters, *A p*, *a m* at right angles to each other, and bisect the radius *o m* in *r*. From the point *r*, with the distance *r A*, describe the arc *A s*, and from the point *A*, with the distance *A s*, describe the arc *s B*. Join the points *A*, *B*, and the line *AB* being carried five times round the circle, will form the pentagon required.

To describe a Pentagon on a given Line.—Make *B m* perpendicular to *AB*, and equal to one half of it.

Draw *A m*, and produce it till the part *m n* is equal to *B m*. From *A* and *B*, as centres with the radius *B n*, describe arcs cutting each other in *o*. And from the point *o*, with the same radius, or with *o A*, or *o B*, describe the circle *ABCDE*. Apply the line *AB* five times round the circumference of this circle, and it will form the pentagon required.—*Note.* If tangents be drawn through the angular points *ABCDE*, a pentagon circumscribing the circle will be formed; and if the arcs be bisected, the circle will be divided into ten parts, which answers to a decagon, and is thus readily constructed.

PENTAGRAPH, or **PARALLELOGRAM**, an instrument whereby designs of any kind may be copied in what proportion you please, without being skilled in drawing. A pentagraph is composed of four bars, *ABDE*, usually of brass; the bar *A* is

joined to *B* at *b* about the middle, and at *a* it is connected with *E*: the bar *B* is the same length as *A*, and at *d* is joined to the bar *D*, whose end is connected with the end of *E*; these four bars form a parallelogram; thus, *ba = D*, and *bd = E*. To the other end of the bar *A*, a tube *F* is soldered, through which

a pointed brass rod *e*, called the tracer, is put; the end of the bar *B* has a slider *G* upon it, which has a tube similar to *F*; another slider, *I*, of the same kind, is mounted on the bar *B*. These sliders have screws, by which they can be fixed at any distance. Under each of the joints of the base, a small tube is fixed, in the bottom of which is a small caster, as *H*, which makes the instrument run easily on the table. When the instrument is used, the two sliders, *G I*, must be set exactly in a line with the tube *F*: when it is required to make a copy of a drawing of the same size, the sliders must be set, so that from *F* to *I* is the same distance as from *I* to *G*; the tube *I* must then have a wire put through it, whose lowest end is fast screwed to a heavy leaden weight *L*, this must have three sharp points in the under side, so that when it is set on the table it may not be liable to move; then, if a design or drawing is laid under the tube *F*, and the point of the tracer drawn over the lines of it, the point of the pencil at *G* will describe a similar figure. If the drawing is to be reduced to one-half of the size, the weight must be put to the slider *G*, and the pencil into *I*, without moving either slider; then the distance from the tracer to the fixed point or weight *L*, is twice the distance of the pencil to the weight. The rule for setting the sliders for any proportion, is as the distance between the tracer *e*, and the fixed point *L*, is to the distance between the pencil *G* and the same; so is the length of any line described by the tracer, to the length of the line at the same time described by the pencil. To avoid the trouble of measuring these distances each time, the bars *B* and *D* are divided into ten or twenty of the most common proportions, by which divisions the sliders are to be fixed. When the machine is used, a fine line, *RR*, is put through rings in the cocks *b d*, and tied to the pencil; the other end has a loop to be hooked over the thumb of the operator, by pulling which he can raise the pencil at *D*, when he does not wish it to mark.

PENTAMETER, in ancient poetry, a kind of verse consisting of five feet, or metres; whence the name. The two first feet may be either dactyls or spondees, at pleasure; the third is always a spondee, and the two last anapests: such is the following verse of Ovid:—

1 2 3 4 5
Carmini | bus vi | ves tem | pus in o | mne meis.

A pentameter verse, subjoined to an hexameter, constitutes what is called elegiac.

PENTANDRIA, in Botany, one of Linnæus's class of plants, the fifth in order; the characters of which are, that all the plants comprehended in it have hermaphrodite flowers, with five stamens, or male parts, in each; they are subdivided into orders, which are denominated monogynia, digynia, trigynia, &c. according as there are one, two, or three, &c. pistils, or female parts, in each flower.

PENTAPETES, a genus of the decandria order, in the monadelphic class of plants, and in the natural method ranking under the 37th order, columnifera.

PENTHORUM, a genus of the pentagynia order, in the pentandria class of plants. There is one species.

PENTSTEMON, a genus of the didynamia angiospermia class and order. There are two species.

PENUMBRA, in Astronomy, a faint or partial shade observed between the perfect shadow and the fall of light in an eclipse. This arises from the magnitude of the sun, for were he only a luminous point, the shadow would be every where perfect; but in consequence of his diameter, it happens, that a place, which though not illuminated by the whole body of the sun, may notwithstanding receive a part of his rays. This may be illustrated as follows: let S represent the sun and M the moon, then it is obvious, since luminous rays proceed from every part of the sun's disc, there will be no part of the shadow in which the light will be totally intercepted, except that included within the rays proceeding from the extreme edges of the sun and moon A B C, and E D C, the other part of the shadow, viz. from C to H, and I experiencing only a partial interception, and consequently in those parts a faint light will be observed, proceeding from the darkest shades at C, diminishing both ways to H and I, where it is lost in perfect light. Penumbrae must be constant attendants of all eclipses whether of the sun, moon, or planets, primary or secondary; but with us they are most obvious in eclipses of the sun, which is the case above alluded to.

PEPLIS, a genus of the monogynia order, in the hexandria class of plants, and in the natural method ranking under the 17th order, calycanthemae. There are two species, creeping plants.

PEPPER, in Natural History, an aromatic berry, of a hot dry quality, chiefly used in seasoning. We have three kinds of pepper at this time in use in the shops; the black, the white, and the long pepper. Black pepper is the fruit of a plant of the diandria trigynia class, without any flower petals; the fruit itself is roundish and rugose, and disposed in clusters; it is brought from the Dutch settlements in the East Indies. The common white pepper is facitious, being prepared from the black. The long pepper is a dried fruit of about an inch, or an inch and a half in length, and about the thickness of a large goose quill; it is of a brownish gray colour, cylindrical in figure, and said to be produced on a plant of the same genus. Pepper is principally used by us in food to assist digestion; but the people in the East Indies esteem it as a stomachic, and drink a strong infusion of it in water by way of giving them an appetite; they have also a way of making a fiery spirit of fermented fresh pepper with water, which they use for the same purpose. They have also a way of preserving the common and long pepper in vinegar, and eating them afterwards at meals.

PEPPER Water, a liquor prepared in the following manner, for microscopical observations: Put common black pepper grossly powdered, into an open vessel, so as to cover the bottom of it half an inch thick, and put to it rain or river water, till it covers it an inch; shake or stir the whole well together at the first mixing, but never disturb it afterwards; let the vessel be exposed to the air uncovered; and in a few days there will be seen a pellicle or thin skin swimming on the surface of the liquor looking of several colours. This is a congeries of multitudes of small animals: and being examined by the microscope, will be seen all in motion; the animals at first sight are so small as not to be distinguishable, unless to the greatest magnifiers; but they grow daily till they arrive at their full size. Their numbers are also continually increasing, till the whole surface of the liquor is full of them, to a considerable depth. When disturbed, they will sometimes all dart down to the bottom, but they soon afterwards come up to the surface again. The skin appears soonest in warm weather, and the animals grow the quickest; but in the severest cold it will succeed, unless the water freezes. About the quantity of a pin's head of this scum, taken up on the nib of a new pen, or the tip of a hair pencil, is to be laid on a plate of clear glass; and if applied first to the third magnifier, then to the second, and finally to the first, will show the different animalcules it contains of several kinds and shapes, as well as sizes.

PEPPERMINT, is a British plant which grows in watery places, and is cultivated chiefly on account of an oil and distilled water which is prepared from it. This is the strongest

and most aromatic of all the mints, and on this account is more used in medicine than any other species. When distilled with water, it yields a considerable quantity of essential oil, of a pale greenish yellow colour. The well-known liquor, called peppermint water, prepared from this plant, is an excellent stomachic; but is too often used in cases of impaired appetite, and for the relief of various imaginary complaints.

PERAMBULATOR, in Surveying, an instrument for measuring distances, called also pedometer, way-wiser, and surveying wheel. The figs 1, 2, and 3 represent a perambulator;

A, fig. 1, is a wheel of mahogany, tired with iron, and made very strong; its circumference must be exactly ninety-nine inches, or half a pole. This is placed so as to turn round in an opening cut in the piece B D, which forms the frame. In the arm B, a groove is cut from the centre of the wheel to the dial *b*; the end of the spindle comes through the wood into this groove, and has a small crown wheel of eight teeth upon it. This works another wheel of eight teeth, fixed on a long spindle, which conveys motion from the wheel beneath to the dial *A*. The groove containing this spindle has a slip of wood screwed over it, to keep out dirt, &c.; and the end of this spindle has a square hole in it, into which is put the square end of the spindle *a*, fig. 2. This has an endless screw *d* upon it, which works a

worm wheel *e* of twenty-four teeth, having a pinion of twelve beneath it, and below this has a wheel *f* of thirty-six. The pinion works the wheel *g* of forty; and the wheel *f* turns the pinion *h* of twelve, whose spindle carries the short hand of the dial, fig. 3. The arbour of the wheel *g* comes up through the dial, and has the hand *F*, fig. 3 on it; as also a pinion of eight, which turns *g* of sixty-four. In the arbor of the wheel *h*, is a pinion of six, taking into *k* of seventy-two; this is here supposed to be half broken away, to show the wheels beneath. The spindle of this is hollow, and is put over the arbour of the wheel *g*, and carries the hand *G*; fig. 2. H H H H are four pillars, by which the two plates forming the frame for the wheels are held together. The wheel *g*, fig. 2 is not fixed fast to its spindle, but is held between a brass plate, and another beneath; the friction of these causes the wheel to turn the hand, and at the same time leaves the hand at liberty to be set without moving the wheels. The plate has a pin fixed in it; which pin takes against a projecting part of the handle of the hammer *m*, so as to lift it up when the plate is turned, and let the spring *p* through *w* against the bell *K*. When any distance is to be measured by this machine, the operator takes hold of the handle, and wheels it along in as straight a line as he can. The circumference of the wheel being ninety-nine inches (or half a pole), and the two wheels in the piece being equal, the screw *d*, fig. 2, will turn once in each turn of the great wheel, or twice for

every pole the machine is wheeled. This screw must be so cut that the great wheel must turn twenty-four times for one turn of the wheel *e*, and also the wheel *f* on the same spindle as this must turn a pinion *h* of one-third of its number of teeth. The short hand on the dial which it carries will for every revolution require eight turns of the great wheel, = four poles, = one chain. The circle is divided into one hundred parts each = one link. The pinion of twelve on the arbor of the wheel *e*, turning once for twenty-four turns of the great wheel, makes the wheel *g* require for each revolution eighty turns of the great wheel, or for the machine to be wheeled ten chains (or turns of the short hand) = 40 poles (as the circle of its hand is divided), = one furlong; and at each revolution of this wheel the hammer *m* will strike the bell *K*. The pinion of eight on the arbor of the wheel *g*, works *h* of sixty-four; and its pinion *i*, turns *K* of seventy-two, the result of which will be, that the hand on the spindle of *h* will require for each revolution 7,680 turns of the great wheel, or for the machine to be wheeled 3,840 poles, = 960 chains or turns of the short hand, = 96 furlongs or turns of the hand *F* and strokes on the bell, = 12 miles, as the dial is divided.

PERCA, *Perch*, a genus of fishes of the order thoraci.

PERCH, in Land Measure, the 40th part of a square rood, containing 30½ square yards.

PEACH, is also sometimes used as a measure of length, being equal to 5½ yards, or 16½ feet, and is otherwise called a rod or pole.

PERCUSSION, in Mechanics, the striking of one body against another, or the shock arising from the collision of two bodies. This is either direct or oblique. *Direct Percussion*, is when the impulse takes place in a line perpendicular to the plane of impact. *Oblique Percussion*, is that which takes place in any direction not perpendicular to the plane of impact.

The *Theory* of **PERCUSSION**, says Barlow, has engaged the attention of philosophers, particularly with regard to the comparison of percussion and pressure, one party maintaining a perfect congruity between these two forces, while others assert their total incomparability, observing, that the least quantity of percussion is greater than any pressure, however great; for, say they, the momentum of a body is measured by its mass into its velocity; if, therefore, the body *A* moves with a velocity *v*, while the body *B* is at rest, or has no velocity, the momentum of the former is $A \times v$, and of the latter $B \times 0$, and consequently the former is infinitely greater than the latter. But without following all the reasonings which are advanced on this subject, we will endeavour to trace the causes of the difference between the effects of impact and that of simple pressure. When a body, perfectly hard, and in motion, strikes another body also perfectly hard, the variation in motion ought to be produced in an indivisible instant, and in such a manner, that between the initial velocity, and the velocity after the shock, there shall not be any intermediate velocity. But were the motion of the body modified by a pressure, or a constant force, as that of gravity, it would change by sensible degrees, and undergo a determinate variation at the end of a certain time. It is, therefore, the law of continuity which distinguishes the effects of compression from those of percussion, when the hardness is infinite; but as such hardness no where exists, matter always possessing a certain degree of elasticity, and limited cohesion of particles, which may be surmounted, we inquire, if percussion, considered physically, conforms to the law of continuity, when a body strikes another, two effects have place in each. First, the parts in contact yield to the action of the stroke, and become compressed, so that the figure of the bodies is altered by a flattening or impression, in the parts in contact, and in their neighbourhood. Secondly, when the flattening or impression has arrived at the greatest degree of which the bodies are susceptible, their inherent elasticity tends to destroy the impression, and effaces it wholly, or in part; this produces a mutual action and re-action, which is continued till the bodies are no longer in contact. Thus, as soon as bodies come into sensible contact, compression begins; as in the case of two balls, which will therefore touch only in one point. The mutual pressure which is necessary to produce the retardation of *A*, and the acceleration of *B*, is exerted only on the foremost particle of *A*, and the hindmost particle of *B*;

but no atom of matter can be put in motion, or have its motion changed, unless it be acted on by an adequate force. And the force urging any individual particle, must be precisely competent to the production of the very change of motion which obtains in that particle. Except the two particles which come into contact in the collision, all the other particles are actuated by the forces which connect them; and the force acting on any one is generally compounded of many forces, which connect that particle with those adjoining. Therefore, when *A* overtakes *B*, the foremost particle of *A* is immediately retarded; the particles behind it would move forward, if their mutual connexion were dissolved in that instant; but this remaining, they only approach nearer to the foremost striking particles, and thus make a compression, which gives occasion for the inherent elasticity to exert itself, and by its re-action retard the following particles. Thus each stratum, (so to conceive it,) continuing in motion, makes a compression, which occasions the elasticity to re-act, and by re-acting, to retard the stratum immediately behind it. This happens in succession: the compression and elastic re-action begin in the anterior stratum, and take place in succession backward, and the whole body gets into a state of compression. All this is done in an instant, (as we commonly, but inaccurately, speak;) that is, in a very small and insensible moment of time; but in this moment there is the same gradual compression, increase of mutual action, greatest compression, common velocity, subsequent restitution, and final separation, as in the case of bodies with a slender spring interposed, or even in the case of mutual repelling magnets. In all the cases, the changes of motion are produced by the elasticity, or the repulsion, and not by the transfusion of the force of motion. The changing force is, indeed, inherent to the bodies, but not because they are in motion; the use of the motion is to give occasion, by continued compression, for the continued operation of the inherent elasticity. Hence it appears that the law of continuity has actually place in the impact of bodies, and that no alteration in their motion takes place without their previously partaking of all the intermediate alterations. This alteration is always produced during an extremely short interval of time, and this occasions the great disproportion observed between the effects of impact and those of pressure; but it is, notwithstanding, inconceivable "that any really existing body should pass from quiescence into finite motion, or from one degree of finite motion to another, without having possessed all the intermediate degrees of velocity;" and hence it follows, that the phenomena of collision may be considered of a kindred class to those which are occasioned by accelerating or retarding forces, and act by insensible degrees, in order to produce a finite effect.

PERCUSSION Powder.—Take two parts of the chlorate of potash, and one of antimony; they must be separately levigated to an impalpable powder, in a marble mortar, and mixed together with an ivory knife: to granulate it, it must be made into a thick paste, with spirit of wine, in which must be dissolved a little gum-mastic, to make it adhesive; and by forcing it through a hair sieve, it will be formed into grains. Four parts of potash, and one of antimony, will detonate; but this mixture was found, after a great number of trials by an eminent chemist, not to be sufficiently strong to be depended upon. To use fulminating mercury is highly dangerous, as the most serious accidents might arise, from its detonating by the slightest friction; and so far from its application to this purpose being a new discovery, it has been used as a percussion powder some years ago.

PERCUSSION Lock, by Wightman, of Malton, Yorkshire.—*A*, the lock plate; *B*, the cock; *C*, a screw, the point of which is made to fit the pan; *D*, the magazine, the chamber of which, that contains the priming powder, is shewn by dotted lines; *E*, a hole in the magazine, through which the roller *F* passes; *G*, a cup drilled to contain 1½ grains of powder; *H*, a small lever, fixed on a square on the end of the roller, and fastened by means of a screw; *I*, a cylinder, screwed into the breech of the gun, and through which a communication is made from the pan into the barrel; *K*, the pan, the size of which is the same as the cup in the roller. To prime this lock, it must first be put to half-cock; then place the magazines on the pan, as is shewn by the figure; and by turning the roller by means of the lever, half a

circle, the priming is transmitted from the magazine into the pan, and the percussion of the screw C, on the priming, causes ignition. To enumerate the qualities of this lock would be

unnecessary; for by a reference to the engraving, its very valuable properties will be sufficiently understood.—*Mech. Mag.*

PERENNIAL, in Botany, is applied to those plants whose roots will abide many years, whether they retain their leaves in winter or not: those which retain their leaves are called evergreens; but such as cast their leaves, are called deciduous.

PERGALESIA, a genus of the pentandria dyginia class and order, of which there are five species.

PERIAGUA, a sort of large canoe, composed of the trunks of two trees, hollowed and united in one fabric: whereas canoes in general are formed of only the body of one tree. The periagua is used in South America and the Gulf of Mexico.

PERICARDIUM, in Anatomy, is a membranous bag filled with water, which contains the heart in man, and many other animals. It is formed by a duplicate of the membrane which divides the thorax into two unequal parts.

PERICARPIUM, among Botanists, a covering or case for the seeds of plants.

PERIGEE, or **PERIGEUM**, in the ancient Astronomy, signified the nearest approach of the sun, or any of the planets, to the earth; or rather, that point of their orbit when at their least distance; a term which the moderns have changed to *perihelion*, because it is the earth that is in motion, and not the sun, as was supposed by the ancients. The term perigee is, however, still properly used, as applied to the moon, comets, &c. to denote their nearest approach to our planet.

PERIHELION, or **PERIHELUM**, that point in the orbit of a planet, or comet, which is nearest to the sun; being the extremity of their transverse axis, nearest to that focus in which the sun is placed; being thus opposed to the aphelion, which is the opposite extremity of the same axis. The perihelion distances of the several planets, the mean distance of the earth from the sun being taken as unity, are as follows:—

Perihelion Distances of the Planets, the Mean Distance of the Earth being Unity.

PERILLA, a genus of the class and order didynamia gymnospermia.

PERIMETER, is the ambit or outward boundary of any figure; being the sum of all the sides in right-lined figures, and means the same as circumference or periphery in circular ones.

PERIOD, in Astronomy, is the time in which a planet or satellite makes one entire revolution in its orbit, or returns

again to the same point in the heavens. It is one of the celebrated laws of Kepler, discovered by observation, and confirmed by Newton in his "*Principia*," that the squares of the periodic times of revolution are to each other as the cubes of the distance of the respective planets from the sun. And the same law has also place with all the satellites revolving about the same primary.

PERIOD, in Chronology, denotes an epoch, or space of time, by which the years are reckoned. See *EPOCH*.

PERIOD, in Grammar, denotes a small compass of discourse, containing a perfect sentence, and distinguished at the end by a point or full stop, thus (.); and its members or divisions marked by commas, colons, &c.

PERIODICAL, returning at stated periods.

PERIOECI, are those who live in the same latitude, but in opposite longitudes; when it is noon with the one, it is midnight with the other; they have the same length of days, and the same seasons of the year. The inhabitants of the poles can have no Perioeci.

PERIOECIANS, in Geography, are those people which inhabit the same parallel of latitude.

PERIPATETIC PHILOSOPHY, the system of philosophy taught and established by Aristotle; the word is derived from the Greek verb, *I walk*, because they always disputed while walking in the Lyceum.

PERIPHERY, in Geometry, the circumference of a circle, ellipsis, or any other regular curvilinear figure. See *CIRCLE*, &c.

PERISCII, are those people who inhabit the frigid zones, so called, because their shadows, during a revolution of the earth on its axis, are directed towards every point of the compass. In the frigid zones, the sun does not set during several revolutions of the earth on its axis.

PERISTYLE, in ancient Architecture, a building encompassed with a row of columns on the inside.

PERJURY, in Law, false swearing, which is punished by the pillory, and by transportation; and this perjury is supposed to be committed in some court of justice having power to administer an oath, or before some magistrate.

PERLATE ACID. This name was given by Bergmann to the acidulous phosphate of soda.

PERLATED ACID, biphosphurate of soda.

PERMIT, a license or warrant for persons to pass with or sell goods, having paid the duties of custom and excise.

PERMUTATIONS, the changes in the position of things; differing from combinations in this, that the latter has no reference to the order in which the quantities are combined; whereas in the former, this order is considered, and consequently the number of permutations always exceeds the number of combinations. Permutation also differs from what is simply termed changes, in this,—that by changes, is commonly meant only the different order in which a number of things may be arranged, taking all together; whereas permutation implies a combination of a number of things into different sets, and the changes which may then have place amongst them. In general, the number of permutations may be found by first finding the number of combinations, and then the number of permutations in each; and the product of these is the whole number of permutations. See *COMBINATIONS*.

PERORATION, in Rhetoric, the epilogue or last part of an oration, wherein what the orator had insisted on through his whole discourse is urged afresh with greater vehemence and passion.

PEROXIDE, in Chemistry, denotes the maximum of oxidation. See *OXIDE*.

PERPENDICULAR, in Geometry, is formed by one line meeting another, so as to make the angles on each side of it equal to each other.

PERPENDICULAR to a Curve, is a line perpendicular to the tangent of the curve at that point.

PERPENDICULAR to a Parabola, is a right line cutting the parabola in the point in which any other right line touches it, and is also itself perpendicular to that tangent.

PERPENDICULAR Action of Gravity, is the direction which it gives to a body falling freely, which is always in a line perpendicular to a tangent to the earth's surface at that point, and not necessarily in a line directed to the centre of the earth.

To erect a Perpendicular upon a given Point C, in a given Line A B.—When the point is near the middle of the line, fig. 1. On each side of the point C take any two equal distances Cn, Cm. From n and m, with any radius greater than Cn or Cm, describe arcs cutting each other in s. Through the point s

Fig. 1.

Fig. 2.

draw the line sC, and it will be the perpendicular required. When the point is at or near the end of the line, fig. 2. Take any point o, and with the radius or distance oC describe the arc mCn, cutting AB in m and C. Through the centre o, and the point m, draw the line mon, cutting the arc mCn in n. From the point n draw the line nC, and it will be the perpendicular required.

From a given Point C, to let fall a Perpendicular upon a given Line A B.—When the point is nearly opposite the middle of the given line, fig. 3. From the point C, with any radius, describe the arc nm cutting A B in n and m. From the points n, m, with the same, or any other radius, describe two arcs cutting each other in s. Through the points C s draw the line CGS, and CG will be the perpendicular required. When the point is nearly opposite to the end of the line, fig. 4. To any point

Fig. 3.

Fig. 4.

m, in the line A B, draw the line Cm. Bisect the line Cm, or divide it into two equal parts, in the point n. From n, with the radius nm or nC, describe the arc CGm, cutting A B in G. Through the point C draw the line CG, and it will be the perpendicular required.

Perpendiculars are best described in practice by means of a square; one of whose legs is applied along that line, to or from which the perpendicular is to be let fall or raised.

PERPETUAL MOTION, is that which possesses within itself the principle of motion; and consequently, since every body in nature, when in motion, would continue in that state, every motion, once begun, would be perpetual but for the operation of some external causes; such are those of friction, resistance, &c.; and since it is also a known principle in mechanics, that no absolute power can be gained by any combination of machinery, except there being at the same time an equal gain in an opposite direction; but that, on the contrary, there must necessarily be some lost from the above causes, it follows, that a perpetual motion can never take place from any pure mechanical combination; yet this is a problem which has engaged the attention of many ingenious men, from the earliest period to the present time, though it has but seldom been attempted by men of science, since the true laws of mechanics have been so well established. The annexed sketch exhibits an idea of a mechanical contrivance to work without intermission, till its parts are destroyed by friction. *abcd* is the section of the reservoir, &c. shewing the wheel, the pump, &c. A B is an overshot water wheel; C D, the working beam; B, the pump; F, a pipe from the top of the pump, through which the water was to fall upon the wheel; C G, an arm, communicating, by means of a crank attached to an horizontal shaft through the centre of the wheel, motion to the lever, or working beam, and so raising water from the reservoir by means of the pump; H I, the water. It was supposed, that the water which had fallen upon the wheel into the reservoir, would be raised by

means of the pump, fall through the horizontal pipe, and so produce a continued rotatory motion. Experiment has, how-

ever, proved its inutility. The machine cannot furnish water enough to perpetuate its motion.

PERPETUITY, is where, if all that have interest join in the conveyance, yet they cannot bar or pass the estates; for, if by concurrence of all having interest, the estate may be barred, it is no perpetuity. 1 Chan. Ca. 213.

PERPETUITY, in the doctrine of Annuities, is the number of years in which the simple interest of any principal sum will amount to the same as the principal itself; or it is the quantity arising by dividing 100, or any other principal, by its interest for one year. Thus the perpetuity at the rate of 5 per cent, is $\frac{100}{5} = 20$ years; and at 4 per cent, $\frac{100}{4} = 25$ years.

PERSECUTION, is any unjust pain or affliction which a person designedly inflicts upon another; and, in a more restrained sense, the sufferings of Christians, or indeed of any others, on account of their religion.

PERSEUS ET CAPUT MEDUSÆ. *Perseus and the Head of Medusa*, one of the northern constellations, which, according to the fables of the Greeks, represents Perseus the son of Jupiter and husband of Andromeda, who signalized himself at the court of Cepheus, by rescuing this princess from a marine monster by means of Medusa's head. When the celestial luminaries which were created "for signs and seasons," became in their movements connected in the mind of mankind with the fate of individuals and the destinies of nations, the conjunction and opposition of the planets were made subjects of joy and lamentation; for blessings or misfortunes were supposed to follow the rising or setting of the unconscious constellations, and the science of the ancient Chaldeans and Egyptians, which was also their religion, introduced a mob of deified mortals, composed of heroes, tyrants, women, and boys. The fears of men were changed into reverence and love, their reverence into the worship of the host of heaven, when mythology seduced them from the religion of the Supreme Being. Cepheus, Perseus, and Hercules, were stationed in the starry heavens, where Cassiopeia and Andromeda have each a portion of the celestial sphere, where Orion leads on the most brilliant of the constellations, and where his eagle had borne the favourite of Jupiter, ages before a place was assigned to the minion of Adrian. Thus may we account for the Egyptian figments concerning the dynasties and the wars of the gods; for the marvels and the monsters which sprang from their allegorical mythology; for the hero worship of the Greeks, and all the clumsy inventions of a degraded superstition among the conquerors of the world. The Milky Way around Perseus is very vivid, being undoubtedly a rich stratum of fixed stars, presenting the most wonderful and sublime phenomenon of the Creator's power and greatness. Köhler, the astronomer, observed a beautiful nebula near the face of Perseus. But the most remarkable phenomenon in this constellation is the variable star *Algol*, which changes continually from the 2d to the 4th magnitude. This star has $11^h 59' 30''$ right ascension in time, and $40^\circ 15' 19''$ declination N. The time taken up from its greatest to its least lustre, is 2 days, 20 hours, and 40 minutes, or about 69 hours. During four hours of this period it gradually diminishes in brightness, which

it recovers in the succeeding four hours; and in the remaining part of the time it invariably preserves its greatest lustre; and after the expiration of this term its decrease commences. Mons. Bode allows seven hours for Algol's reduction from the 2d to the 4th magnitude.

PERSON, in Grammar, a term applied to such nouns or pronouns, as, either prefixed or understood, are the nominatives in all inflections of a verb; or it is the agent or patient in all finite and personal verbs.

PERSONATE, is the representing a person by a fictitious or assumed character, so as to pass for the person represented.

PERSONATÆ, in Botany, the 40th order in the fragments of Linnaeus' natural method, consisting of numerous plants, and whose genera arrange themselves under the class and order didynamia angiospermia of the sexual method.

PERSIAN WHEEL, is a name given to a machine for raising water, which may be turned by means of a stream A B acting upon the wheel C D E according to the order of the letters. The buckets $\alpha, \alpha, \alpha, \alpha$, &c. instead of being firmly fastened, are hung upon the wheel by strong pins, b, b, b, b , &c. fixed in the side of the rim; which must be made as high as the water is intended to be raised above the level of that part of the stream in which the wheel is placed. As the wheel turns, the buckets on the right hand go down into the water, where they are filled, and return up full on the left hand till they come to the top at K; where they strike against the end n of the fixed trough M,

by which they are overset, and so empty the water into the trough; from whence it is to be conveyed in pipes to any place it is intended for; and as each bucket gets over the trough, it falls into a perpendicular position again, and so goes down empty till it comes to the water at A, where it is filled as before. On each bucket is a spring r , which going over the top or crown of the bar n (fixed to the trough M) raises the bottom of the bucket above the level of its mouth, and so causes it to empty all its water into the trough. Sometimes this wheel is made to raise water no higher than its axis; and then, instead of buckets hung upon it, its spokes c, d, e, f, g, h , are made of a bent form, and hollow within, these hollows opening into holes C, D, E, F, in the outside of the wheel, and also into O in the box N upon the axis. So that, as the holes C, D, &c. dip in the water, it runs into them; and as the wheel turns, the water rises in the hollow spokes c, d , &c. and runs out in a stream, P, from the holes at O, and falls into the trough Q, from whence it is conveyed by pipes. This is a very easy way to raise water, because the engine requires neither men nor

horses to turn it. To determine the due relation of the power and the weight, so that this wheel may be capable of producing the greatest effect, the following may be taken as a good approximation. After having fixed the diameter of the wheel, which must be something greater than the altitude to which the water is to be raised; fix also upon an even number of buckets to be hung at equal distances round the periphery of the wheel, and mark the position of their centres of motion in such a manner that they will stand in corresponding positions in every quarter of the circle; conceive vertical lines drawn through the centre of motion of each bucket in the rising part of the wheel; they will intersect the horizontal diameter of the wheel in points at which, if the buckets were hung, they would furnish the same resistance to the moving force as they do when hanging at their respective places on the rim of the wheel. Thus, supposing there were 18 equidistant buckets; then while 8 hung on each side a vertical diameter of the wheel, there would be 8 on the other side, and 2 would coincide with that diameter; in this case the resistance arising from all the full buckets would be the same as if one bucket hung on the prolongation of the horizontal diameter at the distance of $2 \sin 20^\circ + 2 \sin 40^\circ + 2 \sin 60^\circ + 2 \sin 80^\circ$, these being the sines of the common radius of the wheel. To know the quantity of water that each bucket should contain, take $\frac{1}{3}$ of the absolute force of the stream, that is, $\frac{1}{3}$ of the weight of the prism of water whose base is the surface of one of the float-boards, and whose height is that through which water must fall to acquire the velocity of the stream; so have we the power that should be in equilibrio with the weight of water in the buckets of the rising semicircle. Then say, as the sum of the sines mentioned above is to radius, so is the power just found to a fourth term, the half of which will be the weight of water that ought to be contained in one bucket. Lastly, as the velocity of the wheel will be to that of the stream nearly as one to 23, the quantity of revolutions it makes in any determinate time becomes known, and, of consequence, the quantity of water the wheel will raise in the same time; since we know the capacity of each bucket, and the number of them emptied in every revolution of the wheel.

PERSPECTIVE, is the art of delineating objects on any given surface, as they would appear to the eye, if that surface were transparent, and the objects themselves were seen through it from a fixed situation.

To commence with what we hope will be found a very easy way of acquiring a general knowledge of the subject; let the student place himself in a darkened chamber, and there let him make a small hole, not larger than a pea, in the door or window, opposite to some remarkable objects, such as houses or trees, the distance of which should be at least equal to their height, and may with propriety be two or three times that distance; and the experiment will be most agreeably conducted, when the sun shines strongly on the surfaces facing the hole. If a sheet of paper, or any white screen, be placed within the room before the hole, an image of the external objects opposite the aperture will be depicted upon it. The image will be beautiful, although the outline of the objects will not be very well defined, nor their colours very distinct, for reasons which the study of optics will fully explain. The instruction, however, to be derived from the experiment, will for the present object be the same. It will be observed, that the images of all objects are inverted; and to understand this, the student must be reminded of the rectilinear motion of light. The image on the screen can of course be formed only by those rays of light which enter the chamber at the aperture, and it will be admitted that the rays from the top of the external objects cannot proceed in a right line to the screen, unless they proceed to the bottom of the screen; therefore, as each ray carries with it the image of the point from which it issued, the top of the objects must be at the bottom of the screen, and the objects on the left hand will be on the right of the image. That the rays of light from the objects cross each other at the aperture, and spread afterwards as they advance, may be proved by varying the distance of the screen; the size of the image upon which, is enlarged by drawing it back, and lessened by placing it nearer the aperture. The student must further be informed, that if he could trace the image on the screen exactly as it is there delineated,

he would on reversing the screen, have an outline of the external objects in accurate perspective. As the proportions of the several parts, therefore, are not altered by the inverted position of the image, they may be contemplated and compared with the original objects, as if no inversion took place. Suppose the front of a single house to be parallel to the surface of the screen, and its centre very nearly opposite to the centre of the aperture, its image upon the screen will be of the same shape as the front itself is known to have, and its dimensions will be obtained by a rule easily discoverable, for the image will be very nearly as much less than the original, as the distance between the image and the aperture is less than the distance between the original and the aperture. This estimate of the proportion between the image and the object, would not require the qualifying term *nearly*, but would be correct, if the aperture were exactly opposite the centre of the front of the house: but we have supposed the aperture to be nearer one side of the building than the other, in order that the rays from the nearest gable of the house may pass through the aperture. This being attended to there, will be an image of the gable end upon the screen, and the size and shape of this part of the image must be particularly noticed. It will be found that though the gable may be in reality as broad as the front, its image is extremely narrow; that its ground line, instead of being level with that of the front, inclines more and more towards the top as it recedes from the eye, and that the further edge of the inclined roof inclines to this line with a greater degree of inclination than the original is known to have; thus besides the narrowness in point of breadth, the height of the most distant corner of the gable is in the image shorter than the hithermost corner. This visual contraction of surfaces is called *fore-shortening*.

To understand how it happens, let the student suppose a thread stretched from any given point in the most distant angle or vertical edge of the gable, to its image on the screen, or spot on which it would fall by taking a rectilinear course; let another line be supposed to be drawn from an opposite point of the nearest angle of the gable, and it will be perceived that as these lines, like the rays of light, cross the aperture, they will at the screen form but a very narrow opening; and as the breadth of the image cannot be greater than this opening, the breadth of the gable must be inconsiderable on the screen. It will be obvious at the same time, that the more nearly the gable is taken in front, the greater will be the breadth of its image, while that of the apparent extent of the front will be proportionably contracted. The inclination of the ground line of the gable will be explained, by supposing lines to be drawn from the four corners or limits of the gable to their respective places on the screen; for the line which bounds the further side of the gable, must have a less image on the screen than the hithermost, because it is more distant, and at an intermediate distance, any vertical line in the gable must have an intermediate height: therefore there must be in the picture a gradual rising of the ground line towards a point horizontally opposite the place of the aperture:—Now the whole art of perspective consists in observing rules which teach us to discover the diminutions of all objects seen obliquely like the gable end of the house. To render this experiment, and the inferences drawn from it, perfectly clear, it ought to be tried and fully considered. It will then speak to the eye, and the object to be obtained by perspective can scarcely be misunderstood, whereas the impression of mere words is speedily effaced.

To prevent any incorrect inference, we shall however refer to *fig. 1*, where, let *CD* represent the window shutter of the dark-

Fig. 1.

ened chamber, and *g* the aperture in it; *AB* an external object, and *EF* the screen which receives its image. It must be

observed, that the darkened chamber is used only as a means of separating the rays which form an image from any other; and that if the direction of the rays could be ascertained as much before the shutter, as they are here behind it, an image of the original object would be obtained of the same size as that upon the screen, and in its erect position, because the rays have not crossed. Accordingly in the practice of perspective, the rays of light from an object are always supposed to be intercepted as they converge to the eye at some point, as at *k*, between the original object and the eye. In the experiment, therefore, the aperture in the window-shutter must be considered as representing the pupil of the eye, the darkened chamber the chamber of the eye, and the screen the retina, or as a means of rendering visible the pictures which the eye receives of visible objects. We need not observe, that a larger aperture, with a convex glass set in it, would in fact form a camera obscura, and a very distinct image would be painted on the screen, at the focus of the glass; but the experiment would then be less simple, and the direction of the rays not so evident. Without a glass, the distinctness of the picture is sufficient to be agreeable, when the eye has been some time in the chamber.

To consider the foundation of perspective in another point of view, let *ABCD*, *fig. 2*, represent a house, seen by the eye at *N*. The eye *N* is supposed to be opposite the corner *q* of

Fig. 2.

the house; its distance from which is equal to *Nq*, and its height five feet from the ground. The situation of the eye corresponds to that of the hole in the window-shutter of the former experiment, and the picture of the house formed in the eye itself, corresponds to that which the screen received. In this situation, as in every other, straight lines drawn from every part of the house to the eye, represent the direction of the rays which form the images of those parts respectively, and thereby render the house visible. The eye, it must be understood, is considered as fixed upon the point *q*, directly before it, and in order that no sensible deviation may be possible, we may suppose it to be looking through a very small aperture in a piece of thin brass. If now a transparent plane, for example a pane of glass. *KL*, be interposed between the house and the eye, at a short distance from the eye, the whole of the house will be seen through the transparent plane, although the latter is comparatively with the house of very small dimensions, because the rays, in proceeding to their point of convergence at the eye, have approached each other in a proportion inversely as the distance; that is, at half the distance from the object, they only extend over half the space contained between the points of emission; at one-fourth of the distance from the eye, they only take up one-fourth of the space; and the same proportion holds for other distances. Suppose the pane of glass to be within arm's reach of the eye at *N*, and that it is coated with gum-water or isinglass so as to receive the marks of a pencil, without having its transparency destroyed; trace the outlines of the house upon the glass, by observing and following exactly the direction in which they are seen through the small aperture in the piece of brass. When this is done, it will be found that the real or measured extents forming the different external surfaces of the house, are represented by extents modified by the distance and obliquity of these surfaces to the eye—in short, as shewn in the figure, a representation of the house in true perspective will be obtained, in the given situation of the eye. To young persons the difficulty of understanding an explanation of this kind is occasioned by their indistinct perception of the relation between the rays and lines from a real

object, and the projection of those lines upon a flat surface, as a sheet of paper. It appears confusing to them to say that the eye is opposite to the corner q of the house, and yet to represent it at N on one side. Unless this difficulty be overcome, and the mind can form a distinct image of the direction which the line shewn on paper would have if drawn from a real object, perspective diagrams will be contemplated with pain, and the remembrance of them will soon be effaced. We shall therefore propose a little experiment, which we recommend to be tried by those who feel the difficulty alluded to.

Let a small model of a house be made of wood, and to every corner of it which can be seen in any one situation, affix a thread of silk, two or three times as long as the model of the house is high. These threads will represent the rays of light proceeding from the corners $A B C D, f k l m$, of the house, in fig. 2. Let the threads be drawn through a hole in a piece of thin brass, just large enough to admit them to be moved freely. The hole in the piece of brass will represent the eye. Let small weights be attached to the extremities of the threads which have been passed through the hole in the brass: the threads being thus stretched, will form a right line from the house to the brass, and the apparatus will be ready for elucidating the nature of perspective. While the model of the house remains stationary, let the position of the brass be varied, sometimes placing it higher, sometimes lower, at different distances and towards different sides; and let the angles formed by the threads in each situation be attentively considered, by the observer placing himself behind the brass, and supposing himself to regard the house as if he saw it through the hole. Let him, after each remove of the brass, suppose that the threads representing the rays of light, without altering their direction, were to pass through a sheet of paper, interposed at any distance between the brass and the house, and he would find that by drawing lines to join the points thus obtained, an outline representation of the house would be produced, and this representation would be in true perspective. For any one situation it would not be a troublesome matter to perforate a piece of paper, to be slipped upon the threads without distorting them; and for other situations, a good idea of what the representation would be, or, in other words, of the perspective space between any given points, would be obtained by measuring the openings between the threads at equal distances from the brass. After the trial and proper consideration of this experiment, it will be easy to form a tolerably correct idea of the perspective appearance of any object, or assemblage of objects, and not difficult to exhibit that appearance on paper. In perspective diagrams, lines must be drawn to represent the rays, the direction of which in this experiment is indicated by threads, and as the view of an object varies with the point from which it is seen, the situation of the eye, both in height and distance, must be laid down upon the paper on which the perspective drawing of an object is to be made, unless we propose to look at the object itself as through a transparent plane. The question then occurs, how shall the position of the eye be designated on paper?—It can no way be represented so clearly as by placing it on one side, as shewn in the figure, or by placing it vertically beneath the object to be drawn, as represented in fig. 12.

By whatever means the representation $t u$, fig. 2, of an object $A B C D$, is obtained, if the outline be accurate, and viewed at a proper distance, it is plain it will make an outline of the same form in the eye as the object itself: and if the colouring were equally perfect, the eye might mistake the figure for the original. But even when colours are not employed, correct dimensions give the whole a pleasing appearance, and constitute the first great requisite to every good picture.

Having thus endeavoured to explain the nature of perspective, we may next advert to the limits of vision. We may consider the eye, in whatever direction we look, as situated in the centre of a sphere, which we may suppose to be represented by the circle $E K F I$, fig. 3. The hemisphere $E L F$ is behind the eye, and therefore obviously invisible; and it is also certain, that the eye, looking forward horizontally to K , cannot take in at once the whole of the hemisphere $E K F$. So far from this, it cannot take in a larger angle than $S R T$, which is but half a hemisphere, or equal to 90 degrees. And as the rays which the eye takes in, extend all around to an equal distance from the

central ray $K R$, it follows, that the whole of the rays which enter the eye at once, will be in the form of a cone, of which the apex is at the eye; and of such a cone of rays, $S R T$ may be considered as the profile. It is, however, found, that to have an agreeable view of large objects, such as buildings, the angle of vision should not exceed 60 degrees, or one-third of a hemisphere; in other words, that we cannot distinctly see the whole of any object, unless its distance from the eye be at least equal to its height; and the appearance of a picture will be more agreeable, if not made to com-

Fig. 3.

prehend above 45, or at most 50 degrees; indeed, for small objects, or such as do not exceed the length of a foot in any of their dimensions, it is not advisable to exceed an angle of 30 degrees. As a picture, therefore, should never comprise more than the eye can easily take in at one view, a distance of 25 degrees on either side of the point of sight, may be considered a standard limit. Fifty degrees, to the eye at B , are comprehended in the angle $x R y$; and we need scarcely observe, that the measure of an angle, is the space it takes up on the circumference of a circle, which has the point of the angle for its centre; a circle being always supposed to contain 360 degrees. Hence, if the lines forming the angle $x R y$, were extended, the angle $x R t$ would still be only one of fifty degrees, because, whatever were the size of a circle drawn from the point R , through its two legs, if that circle were divided into 360 parts, the number of those parts enclosed by the angle could not be more than fifty.

We shall now proceed to the definitions of the terms used in treating of perspective, and then shew the method of putting into perspective, those forms which may be considered as the elements of all others.

Definitions.—1. An *original object*, is any object whatever, which is rendered the subject of a picture.

2. *Original planes or lines*, are the surfaces or lines of original objects.

3. *Perspective plane*, is the surface on which a picture is delineated.—It may here be observed, that painters regard the frame of a picture merely as an aperture through which original objects are seen; and they therefore consider the perspective plane to be transparent, to admit of this view. It is on this account that the perspective plane is frequently called the *transparent plane*.

4. *Ground plane*, is the earth or surface on which stand the objects to be delineated, as well as the spectator.

5. *Ground line*, is the line on which the perspective plane is supposed to rest.

6. *Visual rays*, are those which, passing through the transparent plane, render original objects visible.

7. *Principal visual ray*, is that which passes through the axis or centre of the eye, and the course of which, therefore, from the perspective plane is shorter than any other, because it is perfectly direct. Its height above the ground line is of course always the same as that of the eye.

8. *Point of sight*, is that fixed point from which the spectator looks upon the perspective plane, when any original object is delineated.

9. *Centre of the picture*, is that point of the perspective plane which is exactly opposite the point of sight, that is, where the principal visual ray enters the transparent or perspective plane. It must, therefore, be carefully distinguished from the mean, or centre of any picture, as it can never exceed the height of the eye from the ground line.

10. *The distance of the picture, or point of distance*, is the distance between the eye and the picture.

11. *Vanishing point*, is the point to which the lines meet in a finished perspective.

12. *The*

weight of the eye, that is, it passes horizontally through the centre of the picture.

Distance of a vanishing point, is the distance from the vanishing point on the picture to the eye of the spectator. It may also be proper to remind some, of the difference between a perpendicular and a vertical line or plane: a vertical point is directly to the centre of the earth; it is therefore at right angles to the plane of the horizon, and is the same with the direction of a plumb line: a perpendicular line is any line which is at right angles to another; it may therefore sometimes be a vertical line, sometimes a horizontal one, or in any other direction according to the direction of the line or surface with which it forms a right angle.

Methods of putting Squares into Perspective.—Suppose a square to be traced upon the ground at some distance before that we find upon admeasurement, the length of each side to be eight feet, and that we are opposite the centre of the east side, at the distance of eighteen feet. We know, that if we wish to obtain what is called a ground plan of this square, we must represent it by a square upon paper, as in Fig. 4, and thus we shall have its real appearance, supposing the eye to be looking down upon it, just as it is in its centre. But looking upon it obliquely as we have stated, and with the eye at the height of six feet from the ground, we are convinced, from the nature of perspective as before explained, that the side nearest to us will make a longer impression upon the retina than any of the rest; the question is, therefore, to obtain the appearance of the whole square, that is, its true form of the image it makes on the retina. In the next place, determine the scale to be observed, that is, what the side shall correspond to a foot of the original; for example, suppose one-tenth of an inch. Then draw a line A B, fig. 5,

Fig. 4.

Fig. 5.

one-tenth of an inch long, and another line H D parallel with the base line, at the height of six-tenths of an inch from it, as a perpendicular from the centre of the line A B, and the point C, in which it cuts the horizontal line, will be the centre of the picture. From C, on the horizontal line, set off the distance at which the square is seen, which will here be eighteen feet of an inch, and the point of distance D, will be obtained. From A, draw the line A C; and from B, the line B C; then from A draw the line A D, and to the point h, in which A D intersects B C, draw a line g h, parallel with the ground line A B; it will A g B h, form the perspective outline of the square required.

Let it be supposed, that the square above described is viewed by an eye situated opposite one of its corners, as in Fig. 6. Draw a base line B L, as before, and on each side of

Fig. 6.

assumed point k, set off half the measured length of the diagonal of the square, viz. half the distance between the corners y, Z, fig. 4. Parallel to the base line, at the height of one-tenth of an inch from it, draw the horizontal line P H D, and raise from k, the perpendicular k C. From F draw the line F C, and from G, the line G C. On each side of the centre set off on the horizontal line the points of distance P D, and on each side of them draw lines to the centre of the base k;

then from a, draw the line a P, and from b, the line b D, and the diagonal view a b f k, of the square, will be completed.

We shall give one more example respecting squares: suppose we have a square pavement, composed of equal alternate pieces of black and white marble; the total number of small pieces to be 144, and each of them one foot square, as

Fig. 7.

Here there will be six black and six white pieces on each side of the square. Suppose the spectator to stand opposite the middle of the third square on the left, and that for greater clearness, the scale be two-tenths of an inch to a foot, with the eye five feet above the ground, but at the distance of eighteen feet as before. Draw a base line r k, and divide a part of it into as many equal divisions as there are squares on one side of the original, as, 1, 2, 3, 4, &c. These divisions, by the scale now adopted, will each be two-tenths of an inch. Draw the horizontal line at the distance of five feet (according to the scale) from the base. From the middle of the space between 2 and 3, raise a perpendicular, and to the point C, in which it cuts the horizontal line, draw lines from the commencement and the termination of the divisions on the ground line, viz. r C and 12 C. From C, set off the distance C D, eighteen feet, for the distance of the eye. Draw the line r D, and from c, where it intersects the line 12 C, draw a line c f, parallel with the base line r k; then will r f c 12, give the boundaries of the pavement. To obtain the reticulations, draw lines from each of the divisions, 1, 2, 3, &c. on the base line, to the centre of the picture C, and from each of the same divisions to the point of the distance D. The lines drawn from the divisions to C, form the right and left sides of the small squares, and the lines drawn from the divisions to D, give the points on the line C D, from which the horizontal lines may be drawn to form the other sides of the squares. Or, after all the lines are drawn from the divisions on the ground line to the centre C, and also the line r D, the remaining sides of the squares may be obtained by drawing parallel lines through the various points in which the part r c, of the line r D, intersects the lines drawn to the centre C.

It is often thought by those who are commencing this study, that representations such as the one now given have no resemblance to the originals; but if they be examined as every picture ought to be examined, opposite to the point of sight and at the distance for which they are drawn, the idea of their incorrectness will disappear; to render the illusion the more complete, the figure should be viewed through a small tube or aperture, to prevent the intrusion of surrounding objects. It must also be observed, that diagrams upon paper have frequently, for the sake of convenience, a vanishing point so near, that the eye has not the power of distinct vision at the distance for which they are drawn. Such designs, therefore, although correct in principle, will not appear correct to the eye unless enlarged.

To put a Circle into Perspective.—The perspective, or oblique view of a circle, is an ellipse, and it is usually obtained by drawing a square of a size just sufficient to contain the circle, and dividing it into small squares, then putting the divided square into the perspective, and drawing within it a line through the corresponding parts of the small squares, and this line will be an ellipse. Thus, to obtain the perspective of a circle E F G H, fig. 8, draw round it the square A B C D. Divide the square into small squares, the number of which should be increased in proportion to the exactness with which the perspective curve must be obtained; draw also the diagonals, C B and A D. Throw the square and reticulations

two those elementary forms which enter into the composition of drawings of every description, we shall be obliged to be concise with the remainder of the subject. The student must be aware how much difference of position affects the visual appearance of objects, and that by a proper attention to this circumstance, the few rules which have been given may be applied to subjects of considerable complication. To acquire a knowledge of the principles of perspective, it is recommended not merely to compare the plates with the printed page; but to copy the diagrams, and, for the sake of greater perspicuity, to do this on as large a scale as may be convenient. Afterwards some treatise especially devoted to the subject may be perused, and perhaps Brook Taylor's and Malton's may be the best; though these authors will require considerable attention, they have the merit of being sure guides.

With respect to shadows, the proper distribution of which give such life to perspective drawings, it may be useful to remark, that the shadow cast by any object covers the precise space which that object would prevent the eye from seeing, if the eye were in the place of the luminous body. The position, therefore, of the luminous body, must always be ascertained, and the shadow to be assigned to any object in a picture, will be a perspective view of the space which the eye would be prevented from seeing if in the place of the luminous body. A few experiments with a candle at night will be an easy mode of gaining a little acquaintance with this subject; it must, however, be observed, that the shadow from a candle is every way larger than that part of the object which intercepts the rays; but in point of breadth, this never happens with the shadows of the sun. The reason is, that the rays from the candle considerably diverge, while those from the sun, on account of the immense distance of that luminary, have no perceptible deviation from parallelism. It must be remembered also, that strong reflections from surrounding objects will diminish the intensity of shades, and that not only the quantity of light which falls on an object, but the quantity which can be reflected to the eye, must be considered.

As it frequently happens that persons have occasion to draw in perspective, who have acquired no theoretical knowledge of the art; for the use of such, a great variety of machines have been constructed. Most of these machines are on optical principles; the camera obscura, which we have already described, is one of them, and the camera lucida is another. In praise of the latter, much has lately been said; but although it must be admitted to be a very portable and beautiful instrument, the acquisition of the proper art of using it, is extremely difficult to all, and to some impossible. Its chief use will be that of affording the means of contemplating the real perspective appearance of objects, and perhaps to obtain the position of a few points, but for very minute delineation it is of little value. For general use, we may venture to recommend an instrument described by Ferguson, to whom the knowledge of it was communicated by Dr. Bevis. It has the advantage of other machines in two points; it may be constructed at a small expense by any tolerably skilful artisan in wood, and the use of it will constantly tend to render the practice of perspective drawing more easy, by the manner in which it produces the measure of surfaces or angles. It will, therefore, better than most other instruments for the same purpose, supply the want of a more extended essay.

The machine in question is represented at Figs. 15 and 16. Fig. 15 is a plan, and Fig. 16 a view of it on a larger scale. The same letters refer to the corresponding parts in both figures. A B E F is an oblong board, and X Y are two hinges, on which the part C L D is movable.

This part consists of two arches, or portions of arches, C M L, and D N L, joined together at the top L, and at the bottom to the cross bar D C, to which one part of each hinge is fixed, and the other part to a flat board, half the length of the board A B E F, and glued to its uppermost side. The

centre of the arch C M L is at D, and the centre of the arch D N L is at C.

Fig. 16.

On the outer side of the arch D N L is a sliding piece, N, (much like the nut of the quadrant of altitude belonging to a common globe,) which may be moved to any part of the arch between D and L; and there is such another slider O, on the arch C M L, which may be set to any part between C and L. A thread C P N is stretched tight from the centre C to the slider N, and such another thread is stretched from the centre D to the slider O; the ends of the threads being fastened to these centres and sliders. It is plain, therefore, that by moving the sliders on their respective arches, the intersection P of the threads may be brought to any point of the open space within those arches.

In the groove K is a straight sliding bar I, which may be drawn further out, or pushed further in, at pleasure. To the outer end of this bar, I, Fig. 16, is fixed the upright piece H Z, in which is a groove for receiving the sliding piece Q. In this slider is a small hole R, for the eye to look through in using the machine; and there is a long slit in H Z, to let the hole R be seen through when the eye is placed behind it, at any height of the hole above the level of the bar I.

Suppose a house, *q s r p*, to be at a considerable distance beyond the limits of the plate, to obtain a perspective representation of it, place the machine on a table, with the end E F, of the horizontal board A B E F towards the house, so that, when the arch D L C is set upright, the middle part of the open space (about P) within it, may be even with the house when the eye is placed at Z, and looking at the house through the small hole R; and then fix the corners of a square piece of paper with four wafers, on the surface of that half of the horizontal board which is nearest the house.

To complete the arrangement of the apparatus for drawing, set the arch upright as in the figure, which it will be when it comes to the perpendicular side T, of the upright piece S T, fixed to the horizontal board behind D. Then placing the eye at Z, look through the hole R at any point of the house, as *q*, and move the sliders N and O, till the intersection of the threads at P, is directly between the eye and the point *q*; then put down the arch flat upon the paper on the board, as at *s t*, and the intersection of the threads will be at W. Mark the point W on the paper with the dot of a black-lead pencil, and set the arch upright again as before; then look through the hole R, and move the sliders N and O, till the intersection of the threads comes between the eye and any other point of the house, as *r*; this being done, put down the arch again to the paper, and make a pencil mark thereon at the intersection of the thread as before; obtain the point *p* in the same manner, and draw a line from that mark to the one at *w*. The line *p w*, thus obtained, will be a representation in true perspective, of the corner *p q* of the house.

By thus bringing the intersection of the threads successively between the eye and other points of the outlines of the house, as *r s*, &c. and putting down the arch to mark the corresponding points, on the paper, at the intersection of the threads, then connecting these points by straight lines, the entire perspective outline of the house will be obtained. In like manner find points for the corners of the doors, windows, &c. and draw the finishing lines from point to point. The perspective drawing thus produced, may then be completed, by shading it according to the manner in which the light is observed to fall on the original.

Fig. 15.

Great care must be taken, during the whole of the time, that the position of the machine be not shifted on the table; and to prevent such an accident, the table or support employed should be perfectly steady, and the machine fixed down upon it by screws or clamps.

It is obvious that a landscape, or any number of objects within the field of view through the arch, may be delineated, by finding a sufficient number of points, and connecting them by straight or curved lines, as they appear in the original objects.

The arch ought to be not less than a foot wide at the bottom, that the eye at Z may have a large field of view through it; and the eye should be then at least ten inches and a half from the intersection of the threads at P, when the arch is set upright. If the eye be nearer, the boundaries of the view, at the sides near the foot of the arch, will subtend an angle at Z of more than 60 degrees, which will not only strain the eye, but will cause the outermost parts of the drawing to have a disagreeable appearance.—To avoid this, it will be proper to draw back the sliding bar I, till Z be fourteen inches and a half distant from P; then the whole field of view through the foot-wide arch, will not subtend an angle to the eye at Z of more than 45 degrees: which will give a more easy and pleasant view not only of the objects themselves, but of their representations upon the paper on which they are delineated. Hence, whatever may be the width of the arch, the distance of the eye from it should be in this proportion: as 12 is the width of the arch, so is 14½ to the distance of the eye (at Z) from it.

If a pane of glass, previously coated with thin gum-water, and dried, be fixed in the arch, a person who looks through the hole at R, may delineate upon the glass the objects which he sees at a distance, and the delineation may be afterwards transferred to paper. By this means will be saved the trouble of putting down the arch to take the position of every point, but it will not be so easy to obtain a correct representation.

PERSPECTIVE Glass, in Optics, differs from a telescope in this: instead of the convex eye-glass placed behind the image, to make the rays of each pencil go parallel to the eye, there is placed a concave eye-glass as much before it; which opens the converging rays, and makes them emerge parallel to the eye. The quantity of objects taken in at one view with this instrument does not depend upon the breadth of the eye-glass, as in the astronomical telescope, but upon the breadth of the pupil of the eye. Reflecting perspective glasses, called by some opera-glasses, or diagonal perspectives, are so contrived that a person can view any one in a public place, as the opera or play-houses, without it being possible to distinguish who it is he looks at. See **OPERA GLASS**.

PERSPECTIVE Plane, is the glass or other transparent surface, supposed to be placed between the eye and the object, perpendicular to the horizon. It is sometimes called the section table, or glass.

PERSPIRATION, in Physiology, the excretion of a fluid through the pores of the skin, and which is usually distinguished into sensible and insensible, or perceptible and imperceptible.

PERU, BALSAM OF. This substance is obtained from the *myroxylum peruiferum*, which grows in the warm parts of South America. The tree is full of resin, and the balsam is obtained by boiling the twigs in water. It has the consistency of honey, a brown colour, an agreeable smell, and a hot acrid taste.

PERUKE. It appears that this term was originally applied to describe a fine natural head of long hair; but whatever has been the ancient use or meaning of the word, it has now almost become obsolete, though it was for more than a century in constant application to those artificial heads of hair, made probably at first to conceal natural or accidental baldness, but which afterwards became so ridiculously fashionable, as to be worn in preference to the most beautiful locks, absurdly shaved off the head to make room for them.

PERUVIAN BARK. See **CINCHONA**. The penetrative effects of Peruvian bark are thus described by M. Delpech, a French merchant of Guayra, in the Caraccas, who in 1817 had stored up large quantities of fresh cinchona, in apartments which were afterwards required for the reception of some travellers as guests. These apartments contained each eight or ten thousand pounds of bark, and in consequence of its fer-

mentation, the heat was much greater here than in the other parts of the house, rendering the place somewhat disagreeable. One of the beds placed in these rooms, was occupied by a traveller, ill of a malignant fever: after the first day he found himself much better, though he had taken no medicine; and in a few days he felt himself quite recovered, without any medical treatment whatsoever. This unexpected success induced M. Delpech to make some other trials: several persons ill of fever were placed successively in his magazine of cinchona, and they were all speedily cured, simply by the effluvia of the bark. It happened that a bale of coffee and some common French brandy were kept in the same place for some months; one of the brandy bottles happened to be uncorked, and on examination it was found to possess a slight aromatic taste, to be more tonic, and very superior to common brandy. The coffee also was much altered; when roasted it was more bitter than common coffee, and left in the mouth a taste similar to that of an infusion of bark.

PETAL, among Botanists, an appellation given to the flower leaves, in opposition to the folia, or common leaves of the plant.

PETARD, in the art of War, a metallic engine, somewhat resembling a high-crowned hat. Its use is in a clandestine attack to break down gates, bridges, barriers, &c. to which it is hung; and this it does by means of the wooden plank attached to it. It is also used in countermines, to break through the enemy's galleries, and give their mines vent.

PETERERO, or **PATTERERO**, a small piece of ordnance used on board ships for the discharging of nails, broken iron, or cartridge shot, on an enemy attempting to board. They are generally open at the breech, and their chamber made to take out to be loaded that way instead of at the muzzle.

PETER-PENCE. An ancient tax of a penny on each house, paid to the pope.

PETEVERIA, a genus of plants belonging to the hexandria class, and in the natural method ranking under the 14th order, *Holoraceæ*.

PETITIO PRINCIPII, in Logic, the taking a thing for true, and drawing conclusions from it as such, when it is really false, or at least wants to be proved before any inferences can be deduced from it.

PETITION. No petition to the king, or to either house of parliament, for any alteration in church or state, shall be signed by above twenty persons, unless the matter thereof is approved by three justices of the peace, or the major part of the grand jury, in the county; and in London, by the lord mayor, aldermen, and common council; nor shall any petition be presented by more than ten persons at a time.

PETRIFICATION, the conversion of wood, bones, and other substances, principally animal or vegetable, into stone. But how this is effected cannot be distinctly unfolded; all that we know certainly, is that the original mass is replaced by earthy or mineral particles. Thus on the north side of the river Esk, a short distance above the paper-mill at Penicuik, near Edinburgh, where the strata usually accompanying the coal formation of this country are exposed, a large portion of the trunk, and several roots, of a fossil tree, are visible. It rises several feet above the bed of the river, as far as the strata reaches, and the roots spread themselves in the rock. It appears as if the tree had actually vegetated on the spot where we now see it. It is, where thickest, about four feet in diameter. The strata, in which the remains of the tree stand, are slate clay, and the tree itself is sand-stone. There is sand-stone below and immediately above the slate clay, and the roots do not appear to have penetrated the lower sand-stone, to which they reach. Small portions of coal were observed where the bark existed, the form of which is distinct on the fossil. Whilst sinking a pit, in 1818, at Mr. Fenton's colliery, near Wakefield, Yorkshire, the workmen, having dug to the depth of eighty-six yards, came to a bed of coal two feet six inches thick, beneath which they found a petrified tree, or rather plant, having no branches, standing upright, but rather inclining to the east. It was six inches diameter at the top; but, as they sunk down, it increased to twelve inches, and at the depth of forty-two feet, seemed to branch out roots to another bed of coal six feet thick. The body was a gray sand-stone, coated round with a black carbonized matter one-tenth of an inch, supposed to be

its bark. A species of siliceous fossil wood was found by a sergeant of artillery, who accompanied Captain Sabine, near the top of a hill in Hare Island, on the west coast of Greenland, in latitude $70^{\circ} 28'$. It had been a part of the trunk of a pine tree, about four inches in diameter. The hill is in the interior of the island, about four miles from the shore, and is considerably more than 900 feet above the level of the sea.

In the paper called the General Evening Post, for March the 17th, 1818, there is an account that had been then received at the Admiralty, of an interesting discovery made in the south of Africa, about twenty miles north of Cape Town. Some persons, in digging, happened to strike upon what appeared a beam of timber; but, tracing it, they found a ship deeply imbedded in the soil. A plank of it has accompanied the account of the discovery to the Admiralty. Several other ships, at different times, and in different parts of the world, have been discovered beneath the surface of the earth. It is recorded by Fulgosa, that in the year 1462, as some men were working a mine near Berne, in Switzerland, they found a ship 100 fathoms deep in the earth, with anchors of iron, and sails of linen, and the remains of forty men. Pairre Naxis relates a like history of another such ship having been found under a very high mountain. The Jesuit Eusebius Newcombergus, in his fifth book of Natural History, says, that near the port of Lima, in Peru, as the people were working a gold mine, they found a ship, on which were many characters very different from ours. Strabo also relates, in his first book, that the wrecks of ships have been found 375 miles from sea. Dr. Plett, in his Natural History of Staffordshire, relates a story, that the mast of a ship, with a pulley hanging to it, was found in one of the Greenland mountains. Is it to be supposed that these ships, which have been found beneath the surface of the earth, were antediluvian ships?

In the parish of Motterton, in the Isle of Wight, bones, which are supposed to belong to one of the mammoths, were discovered. Several of the vertebræ, or joints of the backbone, measure thirty-six inches in circumference: they correspond exactly in form, colour, and texture, with the bones of a similar kind found on the banks of the Ohio in North America. Also, in the parish of Northwood, on the north side of the island, the bones of the crocodile have recently been found by the Rev. Mr. Hughes of Newport. They seem to have belonged to an animal of that species, whose body did not exceed twelve feet in length. Their calcareous nature is not altered; but the bones of the mastodon (found on the south side of the island) contain iron. A considerable quantity of bones of a large size were lately discovered buried in the earth, in the neighbourhood of the village of Tiede, near Brunswick. They were examined by M. Dahne, who appears to have distinguished parts of the skeletons of five elephants. There were nine tusks among them, one of which was fourteen feet in length, another eleven, and many grinders, in which the enamel was arranged exactly as in the teeth of the African elephant. A complete head of a rhinoceros, with the horn and teeth, was also found very little altered, and likewise the horns of two kinds of stags. Mr. Dahne, in endeavouring to account for this accumulation of bones belonging to different animals, supposes that the animals existed in immense islands; that some great revolution of the globe inundated their habitations, and forced them to the highest spot for shelter from the waters; that, the waters still rising, they all perished together; that the perishable parts of their carcases were carried away by the waters, and that an earthy deposition soon enveloped the bones, and left them nearly in the state they are now found.

Mammoths' and elephants' bones and tusks are found throughout Russia, and more particularly in Eastern Siberia and the Arctic marshes. The tusks are found in great quantities, and are collected for the sake of profit, being sold to the turners in the place of the living ivory of Africa, and the warmer parts of Asia, to which it is not at all inferior. Towards the end of the month of August, when the fishing season in the Lena is over, the Tungusians generally go to the peninsula of Tamut, where they employ themselves in hunting, and where the fresh fish of the sea offer them a wholesome and agreeable food. One day, their chief, Schumachof, perceived among the blocks of ice a shapeless mass, not at all resembling the large

pieces of floating wood, which are commonly found there. The following year (1800) he found the carcass of a walrus (*trichechus rosmarus*.) He perceived, at the same time, that the mass he had before seen was more disengaged from the blocks of ice, and had two projecting parts, but was still unable to make out its nature. Towards the end of the following summer (1801,) the entire side of the animal, and one of his tusks, were quite free from the ice. But the summer of 1802, which was less warm, and more windy than common, caused the mammoth to remain buried in the ice, which had scarcely melted at all. At length, towards the end of the fifth year (1803,) the ardent wishes of Schumachof were happily accomplished; for the part of the ice between the earth and mammoth having melted more rapidly than the rest, the plane of its support became inclined, and this enormous mass fell, by its own weight, on a bank of sand. In the month of March, 1804, Schumachof came to his mammoth; and, having cut off his horns (the tusks) he exchanged them with the merchant Bultunof for goods of the value of fifty rubles. Two years afterwards, a Mr. Adams, traversing those distant and desert regions, found the mammoth still in the same place, but altogether mutilated. Wild beasts, such as white bears, wolves, wolverines, and foxes also, fed upon it; and the traces of their footsteps were seen around. The skeleton, almost entirely cleared of its flesh, remained whole, with the exception of one fore-leg. The spine from the head to the os coccygis, one scapula, the pelvis, and the other three extremities, were still held together by the ligaments and by parts of the skin. The head was covered with a dry skin; one of the ears, well preserved, was furnished with a tuft of hairs. Accounts from the banks of the Mississippi state, according to the Philosophical Magazine, that the mammoth has been discovered actually in existence in the western deserts of North America. According to the descriptions given of it, this colossus of the animal kingdom is not carnivorous, but lives on vegetables; more particularly on a certain species of tree, of which it eats the leaves, the bark, and even the trunk. It never lies down, and sleeps leaning for support against a tree. It has rather the shape of a wild boar than of an elephant, and is fifteen feet high. His body is covered by a hairy skin, and he has no horn.

PETROLEUM, is a fluid bitumen, of somewhat greater consistency than naphtha, of black, brown, or sometimes dingy green colour. By exposure to the air it assumes the consistence of tar, and is then called *mineral tar*. This substance exudes spontaneously from the earth, or from clefts of rocks, and is found in nearly all countries, particularly in the East Indies, Italy, France, Spain, Germany, and England. In the neighbourhood of Rangoon, in Pegu, there are several hundred wells of petroleum. These are of square form, and each lined with cassia wood staves. The property of the wells is in the proprietors of the soil, for whom they have been sunk, and are wrought. Some of the wells are of great depth. The oil is drawn from them pure, and in a liquid state, and is conveyed from thence in small jars. The whole annual produce of this district is estimated at more than 400,000 hogsheds. At Colebrook Dale, in Shropshire, there is a considerable spring of petroleum, which was discovered at the depth of about thirty yards beneath the surface of the earth, in digging an archway for the conveying coals from a very deep pit. It was at first found to ooze from between the crannies of the rock, but it soon afterwards poured forth in a considerable stream. The utility of this fluid being known, large iron pipes were formed for the conveyance of it into pits sunk for the purpose of receiving it. From these pits it is conveyed into immense caldrons, in which it is boiled until it attains the consistency of pitch. Since the first discovery of this substance, three different springs of it have broken out. One of these is near the celebrated iron bridge, and the fluid that issues from it is almost pellucid, but at the same time is thicker than treacle. Petroleum easily takes fire, and in burning yields a strong, sharp, and somewhat unpleasant odour; a thick and disagreeable smoke. In cold weather it congeals in the open air. In Pegu, and other parts of the East, petroleum is used in place of oil for lamps. Boiled with a species of resin, it is employed for painting the timber of houses, and covering the bottoms of boats and other vessels. In the latter respect it is considered to be particularly effica-

cious, by protecting the timber from the attacks of marine worms. It is also used by the inhabitants of Eastern countries as a lotion in cutaneous eruptions, and as an embrocation in bruises and rheumatic affections. The ancient Egyptians used it in the embalming of dead bodies. In some countries lumps of earth are soaked with petroleum, and are employed as fuel.

Mineral Tar, or *Barbadoes Tar*, is a kind of fluid bitumen, somewhat thicker than petroleum, and nearly of the consistence of common tar. It is viscid, of a black, brownish black, or reddish colour. In burning, its smell is disagreeable, but less pungent than most of the other kinds of bitumen. Its weight is somewhat greater than that of water. In the West Indies, where this substance is principally found, it is applied to many of the purposes for which the preceding species is used; but its principal repute is considered to be as a sudorific in disorders of the breast and lungs, though this application of it is considered to be very improper. It is likewise used as an external remedy in paralytic disorders.

PETROMYSON, the *Lamprey*, a genus of fishes belonging to the class of amphibia nantes, of which there are eight species. The great lamprey is usually of a brown olive colour, tinged with yellowish-white. It is often three feet long, is an inhabitant of the seas, as its name indeed implies; but in the beginning of spring ascends rivers, in which it resides for a few months, then returning to the ocean. It is viviparous. These fishes fasten themselves with the jagged edges of the mouth to large stones, with the most extraordinary firmness, and may be lifted with the tail to a considerable height, without being made to quit a stone of the weight of even ten or twelve pounds. Their principle of vitality is extremely vigorous and persevering, various parts of the body long continuing to move for some hours after it is divided; and the head will adhere to a rock for hours after the greater part of the body is cut away. In some large rivers of Europe these fishes are taken in vast numbers, and preserved with spices and salt as an article for merchandise. In this country the Severn is the most celebrated river for them, and they are much valued on their first arrival from the sea. They are considered a high luxury for the table, and the life of one of the kings of England will be recollected to have been terminated by his excessive partiality to potted lamprey. The lesser lamprey is about twelve inches long, inhabits also the sea, but is found more frequently in the rivers than the former. It abounds in the Thames and Severn, and is preferred by many to the larger species, as being not so strong in taste. In some years half a million of these fishes have been sold from the neighbourhood of Mortlake, for the Dutch cod and turbot fishery, at the rate of two pounds per thousand.

PETTY BAG, an office of Chancery, the three clerks of which record the return of all inquisitions out of every county, and make all patents of comptrollers, gaugers, customers, &c.

PETUNSE, one of the substances of which porcelain is made, being a kind of coarse flint or pebble.

PEUCEDANUM, or *SULPHURWORT*, a genus of plants belonging to the pentandria class, and in the natural method ranking under the 45th order, Umbellatæ.

PEWTER. An alloy of lead and tin in the proportion of two parts of lead and one of tin, forms the *solder* which is used by plumbers; and, in the proportion of one part of lead to three parts of tin, it constitutes what is called *ley pewter*. The *types* which are used by printers for very large characters, are sometimes composed of an alloy of lead and copper.

PHÆTON, the *Tropic Bird*, in Natural History, a genus of birds of the order anseres, of which there are three species. The common tropic bird is of the size of a widgeon, and the two middle feathers of the tail measure $1\frac{1}{2}$ feet at least. These birds are always found within, or at least, very near, the tropics. They frequently soar to a prodigious height, but generally are near the surface of the water, watching the movements of the flying fish, whose escape from the pursuit of the shark, porpoise, and other enemies beneath, is attended with destruction from the frigate or man-of-war bird, the pelican, and tropic bird, above. They occasionally repose upon the backs of the drowsy tortoises, as the latter float upon the water, and in these circumstances are taken with the greatest ease. They build in the woods, and will perch on trees. They shed their long feathers

every year, and the natives of the Sandwich Islands, where the tropic birds abound, pick them up in great abundance in various parts, and consider them as an elegant material in their curious and elaborate dresses, particularly in their mourning suits. These birds are not admired for food.

PHALANX, in Grecian antiquity, a square battalion, consisting of 8000 men, with their shields joined, and pikes crossing each other, so that it was next to impossible to break it.

PHALENA, *MOTH*, a genus of insects of the order lepidoptera. This genus, like that of papilio, containing a vast number of species, is divided into assortments according to the different habits of the animals.

PHANTASMAGORIA, denotes a remarkable optical illusion, arising from a particular application of the magic lantern. In the exhibition of this spectacle, the audience are placed in a dark room, having a transparent screen between them and the lantern, which screen ought to be let down after the lights are withdrawn, and unknown to the spectators. The lantern being then properly adjusted on the opposite side, the figure intended to be exhibited is thrown upon the screen, which will appear to the observers as if placed in free space, and by altering the distance of the lantern, the figure may be made to appear of any size; which changes in its dimensions are attributed, by the observers, to the distance or proximity of the image, so that at one time it appears to be at an immense distance, and at another to be exceedingly near, and over the heads of some part of the audience. The following is a description of the exhibition of this spectacle, as shewn at the Lyceum theatre, London:—All the lights of the small theatre of exhibition were removed, except one hanging lamp, which could be drawn up so that its flame should be perfectly enveloped in a cylindrical chimney, or opaque shade. In this gloomy and wavering light the curtain was drawn up, and presented to the spectator a cave or place exhibiting skeletons, and other figures of terror, in relief, and painted on the sides or wall. After a short interval, the lamp was drawn up, and the audience were in total darkness, succeeded by thunder and lightning; which last appearance was formed by the magic lantern, upon a thin cloth or screen, let down, after the disappearance of the light, and consequently unknown to most of the spectators. These appearances were followed by figures of departed men, ghosts, skeletons, transmutations, &c. produced on the screen by the magic lantern on the other side, and moving their eyes, mouth, &c. by the well-known contrivance of two or more sliders. The transformations are effected by moving the adjusting tube of the lantern out of its focus, and changing the slider during the moment of confused appearance. It must be again remarked, that these figures appear without any surrounding circle of illumination, and that the spectators, having no previous view or knowledge of the screen, nor any visible object of comparison, are each left to imagine the distance according to their respective fancy. After a very short time of exhibiting the first figure, it was seen to contract gradually in all its dimensions, until it became extremely small, and then vanished. This effect, as may easily be imagined, is produced by bringing the lantern nearer and nearer the screen, taking care at the same time to preserve the distinctness, and at last closing the aperture altogether, and the process being (except as to brightness) exactly the same as happens when visible objects become more remote, the mind is irresistibly led to consider the figures as if they had receded to an immense distance. Several figures of celebrated men were thus exhibited with more transformations; such as the head of Dr. Franklin being converted into a skull, and these were succeeded by phantoms, skeletons, and various terrific figures, which, instead of seeming to recede and then vanish, were (by enlargement) made suddenly to advance, to the surprise and astonishment of the audience, and then disappear by seeming to sink into the ground.

PHARMACY, the art of preparing, compounding, and preserving medicinals. The preservation of medicines morely consists in the application of rules for collecting vegetable, animal, and mineral productions, at certain seasons or under particular circumstances, and of ensuring them against the injuries they would suffer by exposure to light, heat, air, moisture, &c. this, therefore, is the least extensive, and peculiar department of the pharmaceutic art. It is the preparation and

Elevation, Plan, Section, and Details of Bell...

composition of medicinals that constitute the principal objects of the science of pharmacy.

PHARO, is the name of a game of chance, the principal rules of which are: the banker holds a pack consisting of 52 cards; he draws all the cards one after the other, and lays them down alternately at his right and left hand, then the *ponte* may at his pleasure set one or more stakes upon one or more cards, either before the banker has begun to draw the cards, or after he has drawn any number of couples. The banker wins the stake of the *ponte* when the card of the *ponte* comes out in an odd place on his right hand, but loses as much to the *ponte* when it comes out in an even place on his left hand. The banker wins half the *ponte's* stake when it happens to be twice in one couple. When the card of the *ponte* being but once in the stock, happens to be the last, the *ponte* neither wins nor loses; and the card of the *ponte* being but twice in the stock, and the last couple containing his card twice, he then loses his whole stake.

PHAROS, A LIGHT-HOUSE. (See the Plate.) The Pharos of Alexandria, built on a small island at the mouth of the Nile, was in ancient times so famous as to impart its name to all the rest. It was erected by the much celebrated Sostrates, with such great magnificence, that it is said to have cost Ptolemy Philadelphus eight hundred talents. It had several stories raised one over another, adorned with columns balustrades, and galleries, of the finest marble and workmanship. At present nothing is to be seen of the small island where it stood, but an irregular castle, without ditches or outworks of any strength. Out of this clumsy building rises a tower, which serves for a light-house, but the grandeur of the old one has totally disappeared. The famous Colossus of Rhodes served also as a pharos. But as those which have been erected in more modern days, on the shores of our own country, are far more interesting, we purpose giving, under the present word, an account of the erection of the Bell Rock light-house.

England, which is never behind in deeds of mercy, very early attempted, by the erection of the Eddystone light-house, to ward off the dangers of the sunken reef of rocks on which so many vessels have been shipwrecked, and which rendered the navigation of the channel so very hazardous: and Scotland, whether we consider the dangers to be prevented, or the difficulties to be overcome in the execution, can now boast in the Bell Rock light-house, a national work, equal in every point of view to any in the world. If, therefore, England has adorned the name of Smeaton with honours, which it is to be hoped will prove immortal, Scotland ought equally to glory in that of Stevenson.

The reef of rocks on which the Bell Rock light-house is founded, is about 427 feet long and 230 feet broad; at the ordinary height of spring tides it is about 12 feet under water; and from the floating sea-weed, the ridge can be traced 1000 feet farther in a south-westerly direction, when the tides are very low. It is situated on the eastern coast of Scotland, about 16 miles S. by E. from the Red-head; 12 miles SE. from Arbroath; 17 miles N. by E. from the Isle of May; and 38 miles N. by W. from St. Abb's-head. Its geographical position is in $56^{\circ} 29'$ of north latitude, and $2^{\circ} 22'$ of west longitude. The reef presents an exceedingly rugged and uneven surface. The rock is composed of red sand-stone similar to the strata of the contiguous promontory of Red-head, and of the opposite shores of Dunglas in Berwickshire. The present vegetation of the rock consists only of sea plants; some of them not of common occurrence on our coast. It is the occasional resting-place of the seal and the cormorant; and is the chosen residence of numerous marine vermes. At the distance of 100 yards, when the tide is low, the water varies from two to three fathoms in depth. The greatest depth between the rock and the opposite shores of Fife is 23 fathoms. This rock, though a mere spot on the surface of the ocean, produces all the remarkable phenomena of in-shore and off-shore tides, which exist on the projecting coasts of the mainland, or among the Scottish islands.

In the erection of the Eddystone light-house, the dangers and difficulties which were encountered and overcome, owing to the smallness of the surface of the rock, were great and

numerous; and although the surface of the Bell Rock was considerably larger, still, being more sunk, and only discovered at low water, the dangers to be encountered were equally great and overwhelming. Owing to the enlarged diameter of the rock, Mr. Stevenson, the engineer, was enabled to make the masonry of this building more than double the cubical contents of the Eddystone.—The following short table will exhibit to our readers the relative dimensions, &c. of the two light-houses:—

	<i>Eddystone.</i>	<i>Bell Rock.</i>
Height of the rock, about }	Level with high water mark.	Level with low water mark.
Height of masonry above }		
the rock }	70 feet.	100 feet.
Diameter of the first en- }		
tire course }	26 feet.	42 feet.
Cubic contents in feet, }		
about }	13,147.	28,530.
Expense understood to }		
have been about }	£21,000.	Ascertained, £61,331. 9s. 2d.

Very early, no doubt, attempts were made to obviate the dangers of this fatal spot; and accordingly, tradition reports, that the monks of the Abbey of Arbroath erected a bell on the rock, which was to be rung by machinery affected by the flowing and ebbing of the tides, whence the present name of the rock, it is said, took its rise.

About the year 1800, the board of commissioners of the northern light-houses, a body organized in 1788, and to whose labours, which are purely *ex officio*, and without any remuneration whatever, the country is under the greatest obligations, being desirous of erecting a light-house on the Bell Rock, requested Mr. Stevenson, their engineer, to survey the spot. He did so, and reported that he conceived it quite practicable to erect one on the plan of the Eddystone light-house. His first landing on the rock was in the summer of 1800, when the boat's crew picked up a variety of articles of shipwreck, comprising a soldier's bayonet, a cannon ball, a hinge and lock of a door, a ship's marking iron, and part of a compass, several pieces of money, a shoe-buckle, &c.

In the year 1803, a bill for the erection was brought into parliament, but was lost in consequence of its being considered that it embraced too wide a range of coast for the collection of the duty. In the year 1806, another bill was introduced into parliament, and passed into a law. This act provided for a loan to the board of £25,000; and as there were surplus duties to the amount of £20,000 in the hands of the commissioners, the work commenced in 1807, with funds to the amount of £45,000.

From the insulated and distant situation of this rock, the first object of the engineer was to provide a convenient residence for the artificers, while engaged at the work. This was done by mooring a tender off the rocks, and on it a temporary light was exhibited. A vessel was provided for conveying the workmen between the shore and the rock. The outer casing of the building was to be of Aberdeen granite, and the internal part of sand-stone. Quarries were opened near Aberdeen for supplying the one, and at Ringoodie, near Dundee, for supplying the other. The principal establishment on the shore was at Arbroath, where a large yard was enclosed for the purpose of preparing the stones. Barracks were likewise erected for the residence of the workmen when on shore.

It was on the 7th of August 1807, that Mr. Stevenson accompanied by Mr. Peter Logan, his principal assistant, and a few workmen, went off to the Bell Rock, and fixed on the site of the building. They immediately commenced their operations, by cutting away a thick coating of large sea-weed, and tracing the line of the foundation with pick-axes on the rock. At this time it was agreed on, that those workmen who went out to the rock should remain for a month without going ashore. They, on the other hand, fixed their terms at 20s. per week, "summer and winter, wet and dry, with free quarters and victuals when at the rock." Premiums, and the allowance they were to receive for working on Sundays, "they left to the honour of their employers."

At the commencement of this arduous undertaking, two or three hours' labour on the rock was considered a very good

tide's work: and the men were then obliged to collect their tools and implements, betake themselves to the boats, and, often under great disadvantages and with considerable risk and danger, seek refuge in the tender which was moored off the rock. To provide a temporary refuge for the workmen on the rock, in case of any accident happening to the boats, formed part of Mr. Stevenson's original design, and he accordingly lost no time in setting about the construction of a wooden beacon or shelter-house, which we have represented in figure A. This most necessary place of refuge was triumphantly completed in the latter end of September, and, as Mr. Stevenson says, "robbed the rock of much of its terrors, and gave a facility to the works which could not otherwise have been easily obtained." The erection of this temporary shelter-house forms an exceedingly interesting part of the history of this altogether interesting undertaking. Six beams, about 60 feet in length, were fixed upright on the rock, inclosing a space, the diameter of which was 35 feet, while they met in a point at the top. They were fixed at their base by great iron stanchions, weighing about 140 lb. each, which were sunk into the rock about 20 inches, and were wedged with successive slips of fir, oak, and iron: at the top the beams were bolted together, and strongly fastened by hoops of iron, see fig. (*first*) G. The works at this stage depended entirely, it may well be supposed, on the state of the weather: they were obliged therefore to work on Sundays, and by torch-light at night, when the tide permitted. The work was thus carried on under circumstances of peculiar hazard, and several very narrow escapes were made.

The sloop Smeaton, which was used as a tender, at one time broke adrift from her moorings, carrying with her one of the artificers' boats, and from the current of the tides it was utterly impossible she could return until after the rock would be overwhelmed by the sea. At this time there were 32 men on the rock, and the two boats which were left would hold little more than half that number, especially in such a heavy sea. This accident of the breaking loose of the tender, and carrying away of the boat, was only known to Mr. Stevenson and the landing-master: the workmen, sitting or kneeling at their work in the foundation pit, were in perfect ignorance of their perilous situation, till the rise of the sea drove them from the works, and made them seek their respective boats for their jackets and stockings. Their dismay and consternation on beholding two boats only instead of three, must have been great; yet "not a word," says Mr. Stevenson, "was uttered by any one, but all appeared to be silently calculating the numbers, and looking to each other with evident marks of perplexity depicted on their countenances." A pilot-boat, however, bringing letters from Arbroath to Mr. Stevenson, fortunately arrived at this dreadful juncture, and thus being all relieved from the rock, they set sail in search of the tender, which they reached, and got safely on board of, though after a most dreadful passage, in which Mr. Stevenson's face and ears were encrusted with a film of salt from the sea-spray breaking over the bows of the boat.

In the progress of the works in the summer of 1808, a considerable addition was necessary to the shipping establishment. Besides the floating light-ship which had been moored off the rock, a schooner of 80 tons was provided as the principal tender. Stone-lighters of 40 tons were also provided for the conveyance of materials; and three praam boats, each capable of carrying about 10 tons upon deck. These last were employed for removing the stones from the lighters anchored off the rock to the wharfs and cranes on the rock. They were doubly fortified by a water-tight ceiling, or lining, in case of damage by being grounded upon the rock, and were farther prepared for the worst by a number of empty casks, which were stowed under deck, and were of themselves capable of keeping the praams afloat. There were also several attending boats for transporting the artificers from the tender to the rock, and one of them was fitted up as a life-boat upon Gratehead's principle. The moorings of the various craft consisted of chains, with cast-iron mushroom anchors, admirably adapted to the situation. Tracks of iron railways were laid upon one level, along the rough and uneven surface of the rock, on which the great blocks of stone were wheeled upon waggons also constructed

chiefly of cast-iron. The little wharfs were provided with cranes adapted to the peculiarities of the respective situations. A descriptive account is given by Mr. Stevenson, in his work, of the various cranes, sling-carts, stone-jack, winch-machine, and Lewis-bat for quarrying purposes, of the moulds for stone-cutters, pumps, and other machinery, in a detailed manner, extremely interesting to the engineer and the architect.

At first, the whole time of flood-tide was a period of leisure. During such periods, the amusements to which the men resorted were as various as their inclinations. Some, fond of reading, were busily engaged at their books; some, who were more musically inclined, played the violin or the flute; and others amused themselves by fishing. The great evil, however, of which they all complained, and which time itself hardly cured, was sea-sickness. Every nerve was therefore strained to erect barracks for their accommodation upon the beams on the rock, which was at once to relieve them from the constant liability to sickness, and from the danger and perplexity of the movements, both by night and day, in boats to and from the rock.

By strenuous and unremitting exertions, the shelter-house was erected, and the foundation-pit of the building prepared, by the middle of the month of July, in this the second season of the work. The foundation had the appearance of a great circular platform, of compact red sand-stone, measuring 42 feet in diameter, surrounded by an irregular margin of rock, rising from 18 inches to 5 feet. In the work-yard at Arbroath, where the materials were prepared, each stone for the first and second courses of the light-house was accurately marked, so that its relative position in the building on the rock could at once be recognized. The stones were cut of a dove-tail form, on a plan similar to those of the Eddystone light-house. This is very well represented in fig. (*first*) A, which exhibits one half of the second course of masonry.

The foundation stone at the Bell Rock was laid by Mr. Stevenson, with masonic ceremony, on the 10th of July, 1808. About eighty persons were present, and if the situation had been eligible, no doubt some thousands would have attended. After this period the work went on with much alacrity, from ten to twenty blocks of stone being generally laid in the course of a tide. Owing to the use of cranes instead of the mere ordinary apparatus, much precision and facility were given to the operations of the builders, and by the latter end of September the works were brought to a conclusion for the season. The building raised to a level with the highest part of the margin of the foundation-pit, or about five or six inches above the lower bed of the foundation-stone, was computed at 368 tons of stone; consisting of 400 blocks connected with 738 oaken trenails, and 1215 wooden wedges. The number of hours of low-water work upon the rock, this season, was 265, of which number only 80 were employed in building. It was, farther, highly satisfactory to find that the apparatus, both in the work-yard at Arbroath and also the craft and building apparatus at the rock, were found to answer every purpose much beyond expectation. The operations of this season, therefore, afforded the most flattering prospects of the practicability of completing the solid part of the building, or 30 feet of the light-house, in the course of another year. The builders returned to their barracks, and work-yard at Arbroath, for the winter; and, on the tender's entering that harbour, the artificers were greeted with cheers from their friends and comrades on shore, who thronged upon the quays to welcome their return. This season's success, however, was chequered with a cross accident, in the loss of a sailor from one of the stone-lighters.

In the spring of 1809 the operations recommenced; and the building, during the course of this season, advanced with great rapidity. The winter storms had done no injury; the whole of the courses which had been laid, and the shelter-house itself, was, in the third year from its erection, remaining quite secure. The artificers, from this tried stability of the shelter-house, were rendered more confident, and more impatient of the trouble and inconvenience attending landing and re-landing on the rock from the tender: and, therefore, before it was quite fitted up for a barracks, they took possession of it through the day. One evening, however, a gale of wind preventing the boats from taking them off, Mr. Peter Logan, and Mr. Francis

Watt, two of the overseers at the rock, with eleven of the artificers, were necessarily left there for 30 hours, while very often the waves washed over their yet imperfectly formed abode: the mortar gallery below them was carried away by the violence of the storm, and one of the cranes was broken to pieces. Hitherto the operations of the builders were wholly confined to the lower-water work. From the great exertions, however, made by the shipping department in supplying materials this season, the builders were enabled to lay 30 blocks of stone in the course of a tide.

When the building had attained the height of the ninth course, the guy ropes of the usual description of beam crane, became too upright, and it was found necessary to resort to other measures. A new machine, called a Balance Crane, was therefore put in preparation for the use of the works next season. In this, the upright shaft was to be retained in an erect position, by a weight acting on the opposite end of the loaded beam, which was thus to be kept in *equilibrium*.
